The radial distribution of satellites shows large variations from one planet to another. There are some analogies between the Galilean satellites of Jupiter, which extend from 6 to 26 planetary radii, and the five big satellites of Uranus, which extend from 5 to 23 planetary radii. In contrast, Saturn's largest satellite, ► [Titan](#), is located at 20 planetary radii, beyond five midsize satellites. Titan is unique in having a dense neutral atmosphere. Neptune's system is different, because of the capture of the big satellite ► [Triton](#), located at 14 planetary radii. No midsize satellite is found at Neptune except the small Proteus at five planetary radii and the very distant Nereid. Triton's capture might have expelled other regular satellites previously formed in Neptune's equatorial plane.

Definition

The Giotto spacecraft (Fig. 1), the first ESA (European Space Agency) interplanetary probe, was designed to flyby ► [comet Halley](#). Launched on 2 July 1985 by an Ariane-1 rocket from Kourou, Giotto succeeded in approaching the

Giotto Spacecraft, Fig. 1 Giotto spacecraft

cometary nucleus to within 600 km on 14 March 1986. Through its first accurate images of a nucleus and in situ studies of gases and dust particles within a coma, the mission has revealed the complexity of comets. Afterwards, the Giotto spacecraft was reoriented in order to study comet Grigg-Skjellerup, which was flown by on 10 July 1992, at a nucleus distance in the 150–200 km range.

History

Giotto was named after the painter Giotto di Bondone, who, in 1301, depicted a comet as the star of Bethlehem in his fresco Adoration of the Magi in Padua. The comet, easily visible from Europe at that time, was later named Halley, after Edmund Halley understood in 1705 it was periodically reappearing.

Overview

Although comets had been observed for centuries, their knowledge remained limited until the 1986 flybys of Halley by an armada of spacecraft (see below). Giotto, the first independent European mission, provided a close-up view of the cometary nucleus, afterwards described as an icy dirt ball, together with evidence for previously unsuspected properties of its dust particles, found to be under-dense and rich in refractory organics. Giotto was also the first mission to be reactivated after hibernation and to return from interplanetary space for an Earth swingby, which oriented it toward a second comet.

Basic Methodology

At the end of the 1970s, a mission to a comet was mandatory to assess the existence of the nucleus, the properties of the coma, and the solar wind interactions. The expected return in 1985–1986 of the active short-period comet 1P/Halley, the trajectory of which was well known, made it an obvious target for a ballistic flyby. Its retrograde orbit (with respect to that of the Earth and of a space probe) nevertheless implied a huge relative velocity between the comet and any spacecraft, about 70 km s^{-1} . In July 1980, once it had become clear that a sophisticated ► [NASA](#) mission with a flyby of Halley and a rendezvous with another comet would not take place, ► [ESA](#) (European Space Agency) approved a mission specifically dedicated to the study of Halley during its passage in the ecliptic at the orbital node closest to its perihelion, i.e., in March 1986.

The onboard experiments (Fig. 2) were selected in January 1981. They consisted in nine instruments with a total mass of about 60 kg, i.e., one camera, three mass spectrometers (neutral, ion, dust), one dust impact detector, one optical probe, two plasma analyzers, one energetic particles analyzer, and one magnetometer, plus one radio-science experiment. The spacecraft had a cylindrical shape (diameter 1.86 m, height 2.85 m, dry mass 574 kg), with its main cylinder covered by a solar array. It was spin stabilized

(period of 4 s), with the spin axis aligned with the relative velocity vector during Halley encounter. A two-layer aluminum-kevlar dust shield, perpendicular to the spin axis, protected Giotto against high-velocity dust impacts; the despun (to counteract the effect of the spin) parabolic reflector of the high-gain antenna was mounted on a tripod at the other end, in order to be oriented toward the Earth during the flyby.

After 5 years of development and tests, Giotto was launched by an Ariane-1 rocket from Kourou, French Guyana, on July 2, 1985, into a highly eccentric geosynchronous transfer orbit. About 1 day and a half later, its solid-propellant motor was fired at perigee to inject the spacecraft into a solar ballistic orbit that allowed it, after a cruise of about 685 million kilometers, to flyby the cometary target without major trajectory adjustments. The encounter took place on March 13–14, 1986, with a relative velocity of 68.4 km s^{-1} , at 0.89 AU heliocentric distance and 0.98 AU geocentric distance and for a phase angle of 107.05° . The closest approach took place immediately after midnight UT, at $(596 \pm 2) \text{ km}$ distance from the nucleus (Fig. 3).

To allow Giotto to approach as close as possible to the nucleus without being destroyed, a unique international cooperation had been organized. An armada of spacecraft had been launched toward Halley, including besides Giotto the Japanese Suisei spacecraft with a nucleus miss distance of 151,000 km and the Russian spacecraft Vega 1 and Vega 2, respectively, at 8,890 and 8,030 km. The pathfinder concept, developed in cooperation between ESA, IKI (USSR), and NASA (USA), was used to define the photometric center (presumed to correspond to the nucleus) on the images collected by the Vega spacecraft, the positions of which were determined by the American Deep Space Network. The distance of closest approach of Giotto was accurately controlled through this unique effort, allowing the spacecraft to approach the nucleus without being totally destroyed by impacts from dust particles hitting it with a high relative velocity.

Giotto was actually hit by a rather large dust particle 14 s before closest approach, leading by

Giotto Spacecraft, Fig. 2 Giotto onboard experiments

nutatation to a shift of the spacecraft angular momentum vector of 0.9° and to an intermittent Earth data link for 32 min. Two weeks after the encounter, the spacecraft was put into hibernation. After its reactivation in February 1990, it could be established that it had survived with minor

degradation of the Halley flyby. On July 2, 1992, after six orbits around the Sun, Giotto was back in the vicinity of our planet at 23,000 km altitude. The Giotto Extended Mission (GEM) to a second cometary target had already been approved by ESA, and the orbit of the spacecraft was retargeted

Giotto Spacecraft,**Fig. 3** Geometry of Comet Halley flyby

through an Earth gravity assist toward 26P/Grigg-Skjellerup, a Jupiter family comet.

This last flyby took place on July 10, 1992, with a relative velocity of 14 km s^{-1} , at 1.01 AU heliocentric distance and 1.43 AU geocentric distance. While the Giotto scientific payload was fully operational for the Halley flyby, it was only 50% operational for Grigg-Skjellerup and no images were provided by the damaged HMC camera. Nevertheless, the OPE (Optical Probe Experiment), undamaged at the rear of the spacecraft, derived a nucleus miss distance below 200 km, most likely in the 150–200 km range, from the monitoring of the evolution of the brightness under the observational geometry.

Among the huge wealth of unique results obtained by Giotto and GEM missions, many are relevant from an astrobiology perspective.

**Giotto Spacecraft, Fig. 4** Image of Comet Halley nucleus obtained by Giotto

Key Research Findings

The Giotto HMC camera provided the first accurate images of a cometary nucleus. They revealed a slightly reddish irregular object, significantly darker and bigger (about 15 km long and 7.5 km by 8 km wide) than anticipated, with various topographic features (hills, ridges, craters, cliffs, ridge, central depression). Well-defined dust structures with the appearance of narrow filaments were noticed in the inner coma, possibly originating from active regions covering 10% of the surface. The mass of the nucleus was too low

to be derived from the spacecraft trajectory perturbations near closest approach. Nevertheless, estimations of the mass from nongravitational effects (later validated through the ► [Deep Impact](#) mission) and of the shape from imaging yield a density of $550 \pm 250 \text{ kg.m}^{-3}$, typical of a highly porous object (Fig. 4).

The icy component of Comet Halley mostly consisted of water. Independent analyses of the D/H ratio from NMS and IMS (Neutral and Ion Mass Spectrometers) lead to a value in cometary

water of $(3.08 \pm 0.3) \times 10^{-4}$, i.e., twice that of seawater on Earth. However, a large dispersion among D/H ratios in both Jupiter Family comets and Oort Cloud comets was later pointed out, suggesting formations over a long period of time or solar distances. Besides, water on Earth might also have come from icy small bodies formed in the outer asteroid belt.

One of the most unexpected discoveries of Halley's missions was that the dust mass spectrometers (PIA on board Giotto, PUMA on Vega) not only detected rock-forming elements (e.g., Mg, Si, Ca, Fe) but also revealed light elements, like carbon, hydrogen, oxygen, and nitrogen, in agreement with data from one plasma analyzer. This so-called CHON material is, most likely, included in complex polymeric organic molecules. Such refractory organics, the presence of which was later confirmed, e.g., for comets Wild 2 by NASA ► [Stardust mission](#) and Churyumov-Gerasimenko by ESA ► [Rosetta mission](#), had quite likely been formed in the interstellar medium. Besides, the properties of dust particles were varying with distance to the nucleus and with time after ejection, most likely under sublimation and fragmentation processes. Comparisons between the results of OPE and DID (Dust Impact Detector) have shown that, on the average, the geometric ► [albedo](#) of the dust particles was very low (about 0.04) and their density extremely reduced (about 100 kg m^{-3}), suggesting that they mostly consisted of fluffy aggregates.

During the Giotto Extended Mission to Grigg-Skjellerup, fragmentation processes could be suspected, with one event noticed by OPE at about 1000 km distance from the nucleus, tentatively interpreted by the presence of an active fragment (10–100 m size) releasing dust in the inner coma. Altogether, discoveries of (1) porous nuclei that may suffer fragmentation processes and (2) refractory organic molecules in low-density cometary dust particles strongly suggest that the interplanetary dust cloud (also called zodiacal cloud) is permanently replenished by organics-rich fluffy particles. During the ► [Late Heavy Bombardment](#) epoch, the amount of interplanetary dust particles of cometary origin

was likely to be most significantly increased. Their highly porous structure, which leads to a significant deceleration and heat transfer in planetary atmospheres, could have contributed to extraterrestrial delivery of carbonaceous compounds, as still presently collected in the Earth and its environment, within the atmospheres of terrestrial planets.

Future Directions

Cometary flybys and, all the more, the 26-months long ► [Rosetta](#) rendezvous mission have established that the cometary dust particles are irregular aggregates of likely fractal submicron-sized grains, presenting a relative abundance of complex organics of about 50%, in volume and even in mass. Besides, similarities with the CP-IDPs presently collected in the stratosphere and the UCAMMs found in Antarctica snows have been recognized. The future ESA-JAXA ► [Comet Interceptor](#) mission should better point out differences between periodic comets and more pristine dynamically new comets. Further away in time, cryogenic samples of a cometary nucleus should lead to a better understanding of a possible contribution of comets to the origin of life on Earth.

GJ 667C: First System with Multiple Super-Earth Candidates in the Habitable Zone

Nader Haghighipour

Institute for Astronomy, University of Hawaii-Manoa, Honolulu, HI, USA

The M1.5V star GJ 667C (Gliese 667C) is a faraway member of a triple star system. It orbits the central binary GJ 667AB (a K3V + K5V binary system) at a projection distance of ~230 AU. GJ 667C is known to host several super-Earth planets. In 2009, at the international ESO/CAUP exoplanet conference in Porto, the first planet candidate around this star was announced: a hot super-Earth on a 7.2 day orbit. However, it was the subsequent discovery and confirmation of a 4.5 Earth mass planet, GJ 667Cc, in the habitable zone of this star (Anglada-Escudé et al. 2012; Delfosse et al. 2013) that made this system one of the most significant planetary systems known to date. The planet GJ 667Cc is the *first* confirmed potentially habitable planet. Figure 1 shows an artist's rendering of this system.

Reanalyzing the publicly available HARPS spectra of GJ 667C using the HARPS-TERRA software (Anglada-Escudé and Butler 2012) combined with the Doppler measurements from PFS/Magellan and HIRES/Keck spectrometers (Anglada-Escudé et al. 2013) claimed that the planetary system of GJ 667C is dynamically packed and, in addition to GJ 667Cc, this system could harbor two more super-Earths in its habitable zone. Figure 2 shows a schematic of the planets of this system with respect to its habitable

GJ 667C: First System with Multiple Super-Earth Candidates in the Habitable Zone, Fig. 1 Artist’s rendering of the triple star system GJ 667 and planets GJ 667Cb and GJ 667Cc

GJ 667C: First System with Multiple Super-Earth Candidates in the Habitable Zone, Fig. 2 Habitable zone of GJ 667C and its three potentially habitable super-Earths

zone, as it is presented in Anglada-Escudé et al. (2013). As shown here, the candidate planets GJ 667Cf and GJ 667Ce, with orbital periods of 39 and 62 days and masses of 1.94 and 2.68 Earth masses, are also in the habitable zone. Note that of all the planets, only planets b and c are truly confirmed. Indeed in 2014, two studies came out that claimed that the signals previously

assigned to additional planets were actually artifacts coming from the activity of the star (Feroz and Hobson 2014; Robertson and Mahadevan 2014).

The discovery of GJ 667Cc as the first confirmed potentially habitable planet was considered as one of the top ten physics newsmakers of 2013 by the American Physical Society.

Glacial period

Definition

A glaciation or glacial period is a geologically short period of time within an ice age characterized by very low surface temperatures and the advance of glaciers. The term differs from an “ice age” or more properly a “glacial age” that is defined as a long-term period of reduction in the temperature of the Earth’s surface and atmosphere, resulting in an expansion of continental and polar ice sheets.

Overview

Glaciation refers to the process of glacier growth or more generally to the establishment of frigid conditions and large ice caps at a global scale. An ice age is characterized by glacial periods, when temperatures plunge and glaciers advance, and interglacial periods, when temperatures increase and glaciers retreat.

The Earth experienced at least five great ice ages. The first is the Paleoproterozoic Huronian (Melezhik et al. 2013), possibly the first recognized Snowball Earth glaciation on Earth initiated at 2450 and terminated at 2320 Ma or possibly at 2220 Ma. This first glaciation is contemporary to the Great Oxygenation Event, although it is still unclear if it is a cause or a consequence of the oxygenation. It is followed by the Neoproterozoic Cryogenian or Sturtian-Varangian (716.5–635 Ma; Macdonald et al. 2010), the most severe ice age when almost all the planet was covered with ice and “Snowball Earth” conditions prevailed (Kirschvink 1992); the Paleozoic Andean-Saharan (450–420 Ma) and the Karoo (360–260 Ma), and finally the Quaternary ice ages (2.65 Ma to present). Earth probably experienced glaciations also in Archean times with the oldest geological record of a glaciation in the 2.9 Ga Mozaan Group in South Africa (Young et al. 1998) and possible correlated rocks in the West Rand Group of the Witwatersrand Supergroup. Recently de Wit and Furnes (2016) have suggested a

glacial origin for rocks belonging to the ~3.445 Ga felsic volcanic unit at the top of the Hooggenoeg Formation, termed H6 member, but this hypothesis has been opposed by Lowe and Byerly (2020) suggesting non-glacial storm-influenced shallow water sedimentary deposits.

The Quaternary glaciations include well-known glacial periods of 41,000 and 100,000 years, which are related to oscillations in Earth's orbital parameters and subsequent variations in the amount of radiant energy of the Sun which is received by the Earth surface, hypotheses that are summarized in the well-known theory of the Milankovitch Cycles.

Several causes have been proposed to explain planetary glaciations on Earth (the so-called ► [Snowball Earth](#) or Snowball episodes). Huronian glaciations could have been triggered by the rise of the oxygen in the atmosphere and the contemporary loss by oxidation of the greenhouse gas CH₄ (Pavlov et al. 2000). Some of the larger glaciations could have been caused by major tectonic re-arrangements of the continental plates and their effect as a sink of atmospheric CO₂, one of the greenhouse gases able to stabilize the atmospheric temperature (Kasting 1993). This is caused by the well-known Urey reaction (Urey 1952), which combines atmospheric CO₂ with calcium silicate to generate calcium carbonate plus silica:

The tectonic episodes of continental plate re-arrangements could be related to accelerated rifting which increased the burial of organic C and thus the decrease of the CO₂ in the atmosphere (Hoffman et al. 1998) or the clustering of continents at low latitudes (Marshall et al. 1988) enhancing weathering of calcium silicates by acid rains with production of carbonates which worked as a sink for CO₂.

In the past 65 million years, the Earth's climate has undergone significant evolution, including alternating trends of warming and cooling driven by plate tectonic processes (rifting, orogenesis, and

continental drift causing the increase of carbon burial and consequent decrease of pCO₂ in the atmosphere), on timescales of 10⁵–10⁷ years, and higher-frequency change in climate (10⁴–10⁵ years) generated by periodic and quasiperiodic oscillations in Earth's orbital parameters (eccentricity, obliquity, and precession) that affected the distribution and amount of incident solar energy (Milankovitch cycles; Zachos et al. 2001). The drifting of continental masses at higher latitudes (Antarctica and Greenland) and the formation of permanent ice sheets in the last 35 Ma probably amplified the orbital effects on the climate and the generation of high-frequency Quaternary climates.

Glaciations are likely not precluded to Earth, and evidence of glacial phases on planetary surfaces could be indirect evidence of chemical atmospheric evolution and/or active plate tectonics. Morphological features that could have been caused by retreating or advancing glaciers have been observed on the surface of Mars and have been attributed to multiple episodes of glaciation (Kargel and Strom 1992; Dickson et al. 2008). In contrast to Earth's ice ages, those on Mars wax when the poles warm up and water vapor is transported toward lower latitudes and wane when the poles cool and lock water into polar icecaps. NASA's Mars Global Surveyor and Mars Odyssey missions have revealed that a covering of water ice mixed with dust mantled the surface of Mars to latitudes as low as 30° and is now degrading and retreating, indicating that the Red Planet is coming out from an ice age started likely between 2.1 Ma and 400,000 years ago (Head et al. 2003).

Globular Cluster

Nikos Prantzos

Institut d'Astrophysique de Paris, Paris, France

Definition

A globular cluster is a dense spherical collection of 10^5 – 10^6 stars orbiting a galaxy. Their origin is poorly understood. About 160 globular clusters are known in the ► [Milky Way](#), while the giant elliptical galaxy M87 may have up to 10,000. In the case of the Milky Way, they are composed of old (~ 12 Gyr) and thus low-mass stars, with low abundances of elements heavier than He, similar to those of field halo stars. Their high internal density (up to 1,000 stars per pc³ in the cluster core) favors dynamical interactions between stars and makes the survival of any planetary system problematic.

Globule, Nanoglobule

Bradley De Gregorio

Materials Science and Technology Division,
 U.S. Naval Research Laboratory, Washington,
 DC, USA

Definition

In meteoritic chemistry, globules or nanoglobules are microscopic, hollow (but sometimes solid),

Globule, Nanoglobule, Fig. 1 Transmission electron microscopy image of an organic nanoglobule within fine-grained silicate matrix of ordinary chondrite QUE 97008

spherical to irregular organic grains present in the fine-grained matrix of carbonaceous chondrites (Fig. 1). Organic globules have also been reported in ordinary chondrites, Antarctic micrometeorites, interplanetary dust particles, and comets. Globule diameters range from less than 100 up to 2 μm . Many are enriched in [▶ deuterium](#) and/or nitrogen-15 relative to the surrounding bulk [▶ insoluble organic matter](#) (De Gregorio et al. 2013), suggesting formation in extremely cold (less than 20 K) [▶ molecular cloud](#) or [▶ solar nebula](#) environments where such isotopic enrichments of organic matter are theorized to occur (Nakamura-Messenger et al. 2006). Some organic globules may also have formed on asteroid and/or planetesimal parent bodies through organic polymerization, such as the [▶ formose reaction](#), during aqueous processing (Cody et al. 2011).

History

Originally discovered in 1961 in crushed samples of the Orgueil and Ivuna meteorites by George Claus and Bartholomew Nagy (Claus and Nagy 1961), organic globules were initially interpreted as [▶ microfossils](#) indigenous to their host

meteorites. They were “rediscovered” independently by Keiko Nakamura-Messenger in 2002 (Nakamura et al. 2002) and Lawrence Garvie in 2004 (Garvie and Buseck 2004).

Glove Box

Ricardo Amils
Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Definition

A glove box is a sealed container that is designed to manipulate objects in a different atmosphere. Built into the front of the glovebox are gloves arranged in such a way that the user can place their hands into the gloves and perform tasks inside the box without breaking containment. Two types of glove boxes exist: one manipulates hazardous substances, such as infectious disease agents; the other allows manipulation of

substances in an oxygen-free or a high-purity inert atmosphere. It is very useful for the manipulation of strict anaerobic microorganisms.

Glucogenesis

► Gluconeogenesis

Gluconeogenesis

Juli Peretó

Institut Cavanilles de Biodiversitat i Biologia Evolutiva, Universitat de València, València, Spain

Synonyms

Glucogenesis

Definition

Gluconeogenesis refers to the biosynthetic pathway of hexoses from noncarbohydrate substrates such as acetate, glycerol, pyruvate, etc. This can be achieved by conversion of the precursor into an intermediate of ► [glycolysis](#) and the reverse of this pathway (with the appropriate bypass of three irreversible enzymatic steps). The phylogenetic distribution of the gluconeogenetic enzymes suggests an early origin of this anabolic pathway, before the emergence of the different glycolytic pathways.

Glyceraldehyde

Kensei Kobayashi
Yokohama National University, Yokohama, Japan

Definition

Glyceraldehyde is a one of the simplest ▶ [carbohydrates](#) (also called sugars); its chemical

structure is $\text{CH}_2\text{OH}-\text{CH}_2\text{OH}-\text{CHO}$. It is an aldo-triose (three carbon sugar with an aldehyde group). Since the middle carbon atom is stereogenic (connected to four different groups: H, OH, CHO, and CH_2OH), it is a chiral compound and two enantiomeric forms are possible: D-glyceraldehyde and L-glyceraldehyde. Terrestrial organisms largely use only D-glyceraldehyde. D-Glyceraldehyde (as its phosphate ester) plays important roles in sugar metabolism, such as in the Benson-Calvin cycle of photosynthesis and in glycolysis. It can be synthesized by mild oxidation of ▶ [glycerol](#). It is formed in the formose reaction, i.e., the polymerization of ▶ [formaldehyde](#) with a catalyst in basic aqueous solution. It has not been detected in carbonaceous chondrites nor in interstellar space, although the related triose, dihydroxyacetone ($\text{CH}_2\text{OH}-\text{CO}-\text{CH}_2\text{OH}$), has been reported in both. However these interstellar identifications have recently been questioned.

of Technology, Atlanta, GA, USA

Synonyms

1, 2, 3-Propantriol; Glycerin; Glycerine

Definition

Glycerol is a three-carbon organic compound with a hydroxyl group on each carbon atom. It is viscous colorless liquid at room temperature. It is extremely soluble in water and is a component of many lipids, either as part of fatty acid esters or phytanyl ethers. Dissolved aqueous glycerol lowers the freezing point of water. Glycerol, like its phosphate ester, is generally metabolically derived from the reduction of glyceraldehyde 3-phosphate or dihydroxyacetone phosphate.

Glycine

Bernd Michael Rode
Institute for General, Inorganic and Theoretical
Chemistry, Leopold-Franzens University,
Universität Innsbruck, Innsbruck, Austria

Keywords

Amino acids · Chemical evolution · Glycine ·
Origin of life · Peptides · Proteins

Synonyms

Aminoacetic acid; Aminoethanoic acid;
Glycocoll; $\text{NH}_2\text{CH}_2\text{COOH}$

Definition

Glycine is the simplest ► [amino acid](#). It is achiral (see ► [Chirality](#)) and found in ► [meteorites](#) and ► [comets](#), indicating the ease of its abiotic formation. It is catalytic in some peptide formation reactions and can be readily oligomerized under some geochemically plausible conditions.

History

Glycine was first isolated by Henri Braconnot in 1820. Its formation under prebiotic conditions was proven by Miller-Urey type experiments using various types of primitive atmospheric gas mixtures and energy sources.

Overview

Glycine is the simplest amino acid and is formed readily and apparently ubiquitously under various natural conditions. Its pK_a values are 2.35 and 9.78 at 25 °C; in neutral solution, it exists therefore predominantly as its ► [zwitterion](#), $^+\text{H}_3\text{NCH}_2\text{CO}_2^-$.

Glycine has been identified in meteorites and comets (Elsila et al. 2009). Although the detection of interstellar glycine remains controversial (see ► [“Molecules in Space”](#)), the glycine precursor aminoacetonitrile was discovered in SgrB2, a giant gas cloud near the galactic center (Belloche et al. 2008). Glycine could also have formed easily from reactions in the primitive atmosphere under various conditions, such as the classical Miller-Urey setting via electrical discharges acting on an atmosphere of hydrogen, methane, ammonia, and water (Miller 1953), or a carbon dioxide – N_2 – water atmosphere (Plankensteiner et al. 2004), now assumed to have predominated on Earth 3.8 billion years ago. A number of other experiments have also demonstrated the formation of glycine from basic chemicals under the influence of various energy sources. It can be derived via Strecker synthesis from NH_4CN and formaldehyde, as well as directly from the self-condensation of HCN.

Starting from glycine, numerous plausibly prebiotic chemical reactions lead to more complex amino acids which are also important in biochemistry, such as serine and alanine (Choughuley et al. 1975). Hence, glycine may have enabled the formation of complex peptides even before the advent of RNA.

Gneiss

Daniele L. Pinti
GEOTOP Research Center for the Dynamics of
the Earth System, Université du Québec à
Montréal, Montréal, QC, Canada

Definition

Gneiss is a ▶ [metamorphic rock](#) composed of quartz, mica, and feldspathoids. It is the most

characteristic metamorphic rock formed during deep or “regional” ► [metamorphism](#), which means at high temperature and pressure. Typically, gneisses are formed at temperatures higher than 500 °C and at pressures between 2 and 12 kbars which corresponds to the *amphibolite* and *granulite* facies (*metamorphic facies* corresponds to mineral assemblages in metamorphic rocks formed under similar pressures and temperatures). The protolith rock can be felsic ► [igneous rocks](#) (*orthogneiss*) or sedimentary siliceous rocks as sandstone (*paragneiss*). The texture of gneiss is easily identifiable for its *foliation*, i.e., the minerals are aligned and flattened forming typical layers of alternate colors corresponding to quartz (white) and micas (dark). This primary layering can be successively deformed by tectonic stresses creating micro-folding. Because of the high temperatures and pressures, gneisses are normally found at the core of mountain chains (orogens). In Archean terranes, gneisses are common and they testify of the presence of early ► [continental crust](#) sequences such as the ► [Amitsoq gneiss](#) (McGregor 1979). Most famous gneiss sequence is the ► [Acasta gneiss](#) with an age of 4.01 Ga, the oldest preserved rock on Earth.

Goethite

Daniele L. Pinti

Geotop, Research centre for the dynamics of the Earth system, Université du Québec à Montréal, Montréal, QC, Canada

Synonyms

[Limonite](#); [Needle ironstone](#)

Chemical Formula

$\text{FeO}(\text{OH})$

Definition

Goethite is a hydrated iron oxide, or iron oxyhydroxide of the orthorhombic crystal system. Goethite forms by weathering of iron-rich minerals and it is commonly found in soils. It may also be precipitated by groundwater in low-temperature environments (authigenic goethite in marine and lacustrine sediments). Silica-associated goethite has been found in hydrothermal deposits. The occurrence of goethite on planetary surfaces could be used as an indicator of low-temperature weathering with the involvement of liquid water. On Mars, experimental studies (Fish Jr. 1966) have shown that hematite (Fe_2O_3) rather than goethite should be stable on its surface.

Goldschmidt, Viktor Moritz

Pierre Savaton

Université de Caen Basse-Normandie, Caen, France

History

Victor Moritz Goldschmidt (1888–1947) is considered the founder of modern geochemistry, establishing its general laws and principles and making it a new discipline in earth sciences. Among his works, there are researches about mineral metamorphic associations and thermodynamic equilibrium; the laws which determine distribution of the chemical elements on the Earth and their classification as litho- (rock-loving), sidero- (iron-loving), and chalcophile (sulfur-loving); the ionic substitution in mineral; the process of fractional crystallization; and the substitution laws of ions of rare elements. He systematized the use of X-rays in study of composition and structure of crystals. Goldschmidt wrote a manuscript about geochemical aspects of the origin of complex organic molecules on the Earth.

Gram-Negative Bacteria

Ricardo Amils

Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Definition

A Gram-negative bacterium is a prokaryotic cell with a ► [cell wall](#) containing small amounts of ► [peptidoglycan](#) and an ► [outer membrane](#) containing lipopolysaccharides, proteins, and other complex macromolecules. The distinction between Gram-positive and Gram-negative bacteria is based on a differential stain, the Gram stain, which depends on the structure of the cell wall (see ► [“Cell Wall”](#)). After Gram staining, Gram-positive bacteria appear purple and Gram-negative bacteria appear red. This difference in reaction to the Gram stain arises because of differences in the cell wall structure which promote the retention of the purple dye, crystal violet, in the Gram-positive bacteria after decoloring with ethanol, while in the Gram-negative bacteria, the stain is not retained. The Gram stain is one of the most useful staining procedures in microbiology. In addition to the peptidoglycan, Gram-negative bacteria contain an additional wall layer, the outer membrane. This layer is effectively a second lipid bilayer, but in addition to phospholipids and proteins as in the cytoplasmic membrane, it contains polysaccharides. The lipid and polysaccharide are linked to form a lipopolysaccharide complex known as LPS. Unlike the cytoplasmic membrane, the outer membrane of Gram-negative bacteria is relatively permeable to small molecules due to the presence of porins, proteins that function as channels that facilitate the transit of low-molecular-weight substances. The outer membrane is not permeable to proteins and other large molecules. The space between the outer and the cytoplasmic membranes is known as ► [periplasm](#). In the periplasm, important functional proteins like hydrolytic enzymes or binding proteins for transport acting as chemoreceptors can be found.

Gram-Positive Bacteria

Ricardo Amils

Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Definition

A Gram-positive bacterium is a prokaryotic cell whose ► [cell wall](#) consists of mainly ► [peptidoglycan](#) and lacks the outer membrane characteristic of the Gram-negative cells. Bacteria can be divided into two major groups, called Gram positive and Gram negative. The original distinction between both groups was based on the Gram stain, which depends on differences in the structure of the cell wall (see ► [“Cell Wall”](#)). The Gram-negative cell wall is a multilayered structure and quite complex, whereas the Gram-positive cell wall consists of a single type of molecule, the peptidoglycan, which is often much thicker. In Gram-positive bacteria, as much as 90% of the cell wall consists of peptidoglycan, although another molecule, teichoic acid, is usually present in small amounts. The phylogenetic analysis of bacteria has demonstrated that the cell wall structure is phylogenetically consistent: all Gram-positive bacteria form a coherent phylogenetic group. The Gram-positive bacteria are a large group of chemoorganotrophic bacteria. The Gram-positive bacteria can be separated into two subgroups, according to the GC content of their genome. Among the different Gram-positive, low-GC bacteria of industrial interest can be found, including lactic acid bacteria, endospore-forming bacteria (like those belonging to the

Bacillus and *Clostridium* genus), and cell-wall-less bacteria, like the *Mycoplasma*. The high-GC, Gram-positive bacteria group corresponds to the phylum Actinobacteria, some of them producers of antibiotics, secondary metabolites of pharmacologic interest.

Granite

Nicholas Arndt
ISTerre, University Grenoble Alpes, Grenoble,
France

Definition

Granite is a coarse-grained intrusive (i.e., crystallized at depth) ► [felsic igneous rock](#) composed mainly of Si- and Al-rich minerals (quartz and feldspars), with minor amounts of biotite, muscovite, and amphibole. Granitic rocks are the dominant component of the ► [continental crust](#). A granite cannot be a primary melt of the mantle ► [peridotite](#). Its formation (and implicitly that of the continental crust) involves the fractional crystallization of mafic magmas or more commonly, remelting of basaltic or sedimentary precursors (anatexis). Granite has not been reported on planets other than Earth, except as rare and disseminated veinlets in a few lunar rocks. Most granite forms in a two-stage process: The first stage involves partial melting of the lower crust and sometimes of subducted oceanic material (of basaltic composition) to form magmas of intermediate andesitic composition. Andesite, in turn, partially melts to form magmas

of granitic composition. The so-called S-granites are intrusive rocks formed by the partial melting of metasedimentary and metavolcanic rocks within orogenic belts through the process of anatexis.

Graphite

Francis Albarède
Laboratoire de Géologie de Lyon, Ecole Normale
Supérieure de Lyon, Lyon Cedex 7, France

Definition

Graphite is a mineral composed of carbon arranged in graphene sheets of six-atom hexagonal rings and stacked in layers. It is the stable form of crystalline ► [carbon](#) at the Earth's surface and shallow pressure and with increasing pressure converts to diamond, which in the Earth is stable at depths in excess of 150 km. Graphite is a widespread accessory mineral in both terrestrial rocks and meteorites. It may result from the inorganic reduction of carbon dioxide and carbonate, notably by hydrogen, or from the dehydrogenation of organic materials at temperatures in excess of 300 °C. Typically, it crystallizes during metamorphism from precursor carbonaceous material or forms from fluid deposition as a precipitate of $\text{CO}_2\text{--CH}_4\text{--H}_2\text{O}$. It coexists with methane-rich gases over a broad range of temperatures. The discovery of ^{13}C -depleted graphite in 3.8 Ga-old rocks from West Greenland triggered a controversy over whether they represent carbon from early organic remains or inorganic precipitates.

Gravity

Definition

Gravitation is one of the four fundamental forces of physics. It causes an attraction between any two massive bodies which is proportional to their masses.

Overview

Gravitation is a property of space which modifies the velocity of massive bodies under its influence. Then, by using Newton's definition, it is a force.

In the context of classical (i.e., nonrelativistic) physics, this same Newton gave a formula for gravity as a fundamental example of his theoretical work between 1666 and 1687. This is the

famous inverse-square law: the force produced by a point-like body of mass m_A located at the position A on another point mass m_B located at the position B is given by Fig. 1.

The second formulation, in which the squared distance d^2 appears, is the more popular but needs to introduce the unit vector $\vec{u}$ in the direction from one mass toward the other.

If an apple falls, its velocity changes: from zero when it leaves the tree to a certain value when it reaches the ground. This apple is thus subject to a force.

If the Moon orbits around the Earth, it is also because its velocity is slightly modified at each instant, by changing its direction in order to close its orbit. As the apple, the Moon is thus subject to a force. Newton had the idea to consider that these two forces are of the same nature: they are of gravitational origin.

On one hand, situated on the surface of the Earth and at one Earth radius ($\sim 6,400$ km) from its center, the apple falls 5 m in 1 s. On the other hand, each second, the orbit of the Moon moves away from a straight line by 1.4 mm. Finally, Newton knew that the Moon was located at a distance representing 60 times the radius of the Earth. The apple, which is then nearer to the Earth by this same factor, feels an effect which is $5/0.0014 \sim 60^2$ stronger, hence the inverse-square law! The other quantities which appear in the formula are the respective masses of the interacting bodies and Newton's universal gravitational constant G , needed to fix the intensity of the force. Newton didn't precisely know the value of this constant; its measure requires precise and refined experiments. One of the first values, $G = 6.7 \times 10^{-11} \text{ m}^3 \text{ kg}^{-1} \text{ s}^{-2}$, was obtained by using a torsion balance and was proposed by

Gravitation, Fig. 1 Definition of the geometrical quantities in the Newtonian gravitational force

Cavendish in 1798. This is why some texts refer to Cavendish's constant. The modern value, $G = (6.67428 \pm 0.00067) \times 10^{-11} \text{m}^3 \text{kg}^{-1} \text{s}^{-2}$, was recommended in 2006 by the CODATA (see Mohr et al. 2006).

The more complete description of gravitation is Einstein's theory of general relativity. This formulation confirms the deep relation between gravitation and space, including its temporal dimension, which is absent in the Newtonian theory. The refinements introduced by Einstein are fundamental for theoretical physics, but in most astrophysical cases, the Newtonian formulation of gravity allows a correct description of the general properties of the system (the Newtonian theory breaks down, e.g., in the vicinity of a black hole).

The form of the gravitational force equation is equivalent to the electrostatic one (Coulomb's law), but in the latter case, the masses are replaced by electric charges and Newton's constant is replaced by $(4\pi\epsilon_0)^{-1}$ where $\epsilon_0 = 8.854 \times 10^{-12} \text{A}^2 \text{s}^4 \text{kg}^{-1} \text{m}^{-3}$. Due to their same spatial dependency, the ratio of the electrostatic force to the gravitational one between protons and electrons depends only on fundamental constants and is independent of the distance. Its magnitude, of order 10^{40} in favor of electrostatics, makes gravity irrelevant for most chemical problems. Nevertheless, as masses are always of the same sign, gravity is always attractive, whereas the electrostatic force can be repulsive. It must be noted at this point that in general relativity, repulsive gravity can appear; it is caused by the so-called dark energy and could be relevant for dynamics at a very large scale, such as in galaxy clusters or in the context of the primordial universe.

This purely attractive behavior of the classical gravitational force represents the main characteristic of gravity; although it is the weakest fundamental interaction, it cannot be screened. This feature allows gravity to build and shape objects on very large spatial and temporal scales.

Pure gravitational problems are generally classified according to the number of interacting bodies. On one hand, two-body problems and their perturbations are the domain of celestial mechanics. On the other hand, when the number of

interacting bodies is more than, say, several thousands, like in star clusters or cluster of galaxies, one deals with a sort of self-gravitating gas and thermodynamics law may be used. There also exist systems for which gravity is only one among the fundamental interactions that must be considered. That is especially the case for stars or large gaseous planets on which gravity acts to keep the matter confined, whereas internal pressure pushes it outward. The balance between these opposite forces produces, at equilibrium, a star or a planet. The different states in which we observe stars correspond to the different types of pressure (thermodynamical, degeneracy) that must be considered to balance the gravity associated to their respective masses. The isotropic character of gravity is at the basis of the spherical aspect of large gaseous planets or stars. In the case of telluric planets, the situation is more complicated: gravity produces a sphere as soon as the body's radius exceeds some hundreds of kilometers.

The Two-Body Problem and Its Perturbations

The academic two-body problem deals with two point masses A and B evolving in empty space and interacting only through their reciprocal Newton force (see Fig. 1). This problem was solved by Newton in 1687. The defining equation is

$$\frac{d^2 \vec{r}}{dt^2} = -\mu \frac{\vec{r}}{|\vec{r}|^3}$$

where $\vec{r}$ is the vector distance between the masses (the distance AB in Fig. 1) and μ depends on the chosen reference frame. In celestial mechanics, one of the two bodies (say A) is generally much heavier than the other. If we consider the reference frame in which A is at rest, one has $\vec{r} = \vec{AB}$ and $\mu = G(m_A + m_B)$. The solution $\vec{r}(t)$ of this problem is a conic curve, the nature of which depends on B 's total energy E_B . This energy is the sum of B 's kinetic energy which is positive and of B 's potential gravitational energy which is by definition negative. If $E_B \geq 0$, the conic is a

hyperbola or a parabola with focus A and the curve is open. If $E_B < 0$, the conic is an ellipse with A at one focus (this case includes the circle), and the curve is closed. Open trajectories are quite exceptional; ellipsoidal is the rule. In the solar system, all the planets lie on such orbits, as do satellites around planets. This configuration provides an equilibrium state between the central force imposed by gravity and the centrifugal one due to this kind of orbit. This last remark explains why the velocity of B is not uniform: Near the focus (planet at perihelion for motion around the Sun), gravity is strong and must be balanced by a large velocity; on the contrary, at aphelion, the velocity reaches a minimum. Such elliptic orbits are periodic with a period $T = 2\pi(a^3/\mu)^{1/2}$ where a is the semimajor axis of the ellipse. This relation is the well-known Kepler's third law.

When B is not a point mass and if its extension is large enough with respect to the gradient of the gravity field, tidal effects can occur. The principal tidal effect is an elongation produced by the stretching (see the entry “► [Roche Limit](#)”). This elongation, combined with B 's own spin at an angular velocity ω , produces a torque (in green on Fig. 2b). This torque accelerates or decelerates the spin of B until ω reaches the value of B 's angular velocity of revolution Ω around A .

This is the reason why the Moon always shows the same face to the Earth: Because of the tidal effect from the Earth, the Moon takes the same time to rotate around its axis as it does to revolve around the Earth. This phenomenon is called synchronisation. The reciprocal effect (from Moon to Earth) makes Earth rotate more slowly on itself: The length of the day actually increases by 2 m per

Gravitation, Fig. 2 Cartoon describing the two major tidal effects

Gravitation, Fig. 3 Principal effects of a radial perturbation on the elliptical two-body problem

century. For instance, at the end of the Neoproterozoic (~900 million years ago), each year on Earth was lasting 481 days, 18 h. Tidal effects can also circularize the orbit of planets or satellites that were initially in an eccentric orbit. This last phenomenon is generally less effective than the previous one and only takes place for planets or satellites in the inner solar system. It does seem to occur for short-period exoplanets.

Perturbations of the two-body problem occur when the source of the potential (essentially A) cannot be considered as a point mass or when other bodies must be considered. Generally, small perturbations produce a precession of the perihelion and a rotation of the orbital plane. The intersection, called line of nodes, between a reference plane (the ecliptic for planets moving around the Sun) and the orbital plane then generally rotates (Fig. 3).

For example, the Sun produces a precession of the Moon's perigee (closest approach to Earth) and a regression of this orbit's line of nodes around the Earth. These two motions have the same period of about 18 years. Most of the motions in solar or stellar systems can be explained using Newton's theory coupled with perturbations and tidal effects. The only "remarkable" exception is the 42 arcsec per century motion of Mercury's perihelion, which has been explained by Einstein's theory of gravity.

Definition

The main scope of gravitational biology is the identification understanding of the effects of gravity on organisms. Main emphases are the identification of gravity sensing systems as well as the analysis of gravity-sensitive responses on all biological organizational levels. This includes the clarification of the role of gravity during evolution and also during individual development, in the course of which gravity has shaped life and provides an essential cue for spatial orientation and the development of polarities.

History

The origin of the discipline "Gravitational Biology" might be set at the nineteenth century, when Julius Sachs (1868), Charles Darwin (1880), and Wilhelm Pfeffer (1904) started to investigate the influence of gravity on plants by demonstrating the role of the root cap in downward growing

plants (gravitropism: growth response in relation to the gravity vector). Sachs and Pfeffer already constructed machines (centrifuges and clinostats, see “[Basic Methodology](#)”) in order to change the influence of gravity and observed the resulting gravity-dependent responses.

Overview

Gravity is one of the most important environmental factors which organisms use for orientation and adaptation to their environment to optimize exploitation of resources. In contrast to all other environmental factors such as light/radiation, temperature, and humidity, gravity has always been constant in direction and strength during evolution of life. Gravity sensing mechanisms have evolved early in the phylogenesis of organisms. By studying the influence of altered gravity by increasing or decreasing Earth gravity (see “[Basic Methodology](#)”), obvious effects such as gravitaxis (orientation of free-moving organisms with respect to gravity), gravitropism (orientation and growth direction of sessile organisms), and general physiological changes (see “[Key Research Findings](#)”) have been identified. However, much remains to be learned about the impact of gravity on basic mechanisms and about possible countermeasures against effects which occur during the absence of gravity under ► [microgravity \(weightlessness\)](#) conditions.

Basic Methodology

Ground-based studies under conditions of hypergravity (by the use of centrifuges) or simulated microgravity (weightlessness) (by, e.g., the use of 2-D and 3-D clinostats/random positioning machines) have identified and brought deeper insights into gravity-induced biological effects. Subsequently, these studies have to be verified in real microgravity (free fall, near weightlessness). Exposure time ranging from seconds to several minutes are achieved, e.g., in a drop tower, parabolic aircraft, and during ballistic rocket flights. Long-term studies (weeks to months) require the

use of orbiting spacecraft such as satellites (e.g., Foton, Bion, or Compact Satellites) or space stations (e.g., MIR, ISS). The methodology for analyses depends on the issue under investigation and ranges from qualitative video observation via (high-end) microscopy to quantitative molecular biology and high-throughput technologies (Omics). Control experiments are necessary to identify microgravity-related effects and exclude potential non-gravitational responses, e.g., due to launch conditions (hypergravity and vibration).

Key Research Findings

Studies to identify the influence of gravity on living matter cover all organizational levels including isolated proteins, single cells, tissues, and whole organisms. While the primary receptors and mechanisms of graviperception are remarkably similar in evolutionary very diverse biosystems, they differ in their gravitational responses. Visible reactions range from movement reorientation to directed growth responses and from physiological reactions to gene regulation.

Cellular and Molecular Biology

The observation that already unicellular organisms (protists, protozoa) can swim to the top of a completely filled and sealed tube by means of gravitaxis has been made more than a century ago. A real breakthrough in understanding the underlying mechanisms came with technologies designed in order to alter the influence of gravity and methodological advances such as image analysis of cellular behavior as well as biochemical approaches.

Due to current knowledge, the principle of cellular graviperception is sedimentation of a mass, which may either be a heavy statolith or the whole content of the cell heavier than the surrounding medium to operate on a gravireceptor either by exerting pressure and contact or by pulling on cytoskeletal elements. In many cases, the receptor seems to be a mechanosensitive ion

channel activated by the gravitational force followed by gated ion flux across the membrane and in turn activation of a sensory transduction chain. The subsequent responses to the gravity stimulus differ widely, ranging from the activation of enzymes or gene expression to physiological reactions, orientation movements, and directed growth.

Animal Biology

Spatial orientation and development of animals requires the complex processing of a variety of stimulus inputs by means of specific receptors. Thus it seems likely that altered gravity impairs the physiology of organisms on numerous levels. Microgravity affects early developmental processes; however, regulatory capabilities are able to correct and compensate at least some of these modifications via more or less unknown mechanisms, resulting in an apparently “normal” adult animal compared to the Earth-grown control. Experiments employing aquatic vertebrates yielded critical periods for the development of the vestibular system. Multiple adaptive effects of altered gravity on the development of the neuro-vestibular system in aquatic vertebrates

have been found, especially regarding the neural control of inner ear otolith mineralization in fish (Fig. 1). A closer understanding of the reasons for (human) motion sickness susceptibility was gained by these experiments. In general, the findings support the “otolith asymmetry hypothesis” which relates motion sickness to differential sensory input from the left and the right inner ear. Thus, numerous experiments on fish as model system have shown that particular neuroscientific issues can be transferred to human physiology.

Plant Biology

Plants demonstrate in a fascinating and easily detectable way the impact of gravity on biological systems (Fig. 2). Considerable progress on the basic knowledge of plant gravity sensing and gravitropism has been achieved regarding especially the basic knowledge on the effects of altered gravity (gravitational stress) on essential cellular functions related to plant growth and development. Experiments performed in microgravity have greatly contributed to the understanding of how plants sense the direction of gravity and respond to it. As a simple unicellular system the green alga *Chara* shows a very pronounced gravitropism,

Gravitational Biology, Fig. 1 Otolith mineralization is affected by gravity. Note that a fish otolith grown 3 weeks at 3xg hypergravity (right image, hg) has a core (indicating the begin of the experiment) as small as in a control reared

at Earth gravity (left image, 1xg), but did not grow that large under hypergravity (1xg, left: 175 μm ; hg, right: 115 μm). (Photo: Marion Beier)

Gravitational Biology, Fig. 2 Gravity as a reliable stimulus for the orientation of plants resulting in gravitropism. (Photo: Vanessa Berghoff)

which is based on the directional growth of the opposite flanks to the cell tip. The tip growth of the cell is controlled by the gravity-dependent displacement of statoliths (small grains of barium sulfate), which get into contact with gravireceptor proteins in the lower cell membrane. Gravireceptor activation in gravistimulated rhizoids induces a local reduction of cytosolic calcium at that area where the statoliths sediment. This causes a local inhibition of exocytosis, which results in a differential extension of the opposite cell flanks and the gravitropic response of the rhizoid, namely, the correction of the growth direction.

Arabidopsis thaliana has become the model system of choice to examine gravity-related responses and regulation in higher plants due to the availability of genomic information. While the gravitropism of roots and shoots of higher plants has been well known for over a century, a detailed understanding of the signal perception and transduction has not yet been achieved. Already Charles Darwin identified the root cap as well as

starch containing particles (amyloplasts which serve as statoliths in the root cap) as important for gravitropism. Another line of evidence showed that a phytohormone, auxin, is involved, too. A differential displacement of auxin was identified as main cause for the reorientation growth of plant organs in respect to gravity (but also to other stimuli like light). The current model of gravitropism is based on the differential transport of auxin due to specific membrane proteins (PIN proteins). In roots, auxin is transported in the direction of root caps by the combined action of several PIN proteins. The location of one of the PIN proteins in the membrane changes according to the orientation of the root. As a result the concentration of the auxin increases in the lower half of a gravistimulated root. However, this model includes many unproven hypotheses and the current view might well change in the future.

Applications

Application of gravitational biology aims at the solution of terrestrial and space-related challenges. Assuming that gravisensation is a general capacity of each type of cell, translational research from the cellular level to a medical application provides new aspects of research. Identified issues include the progressive atrophy of bones and muscles as well as the reduced stimulation of immune cells. The recent attempts to understand the microgravity-induced alterations on the molecular and cellular level increase our knowledge in basic life science and might well contribute to human health considerations. Development of countermeasures against, e.g., depression of the immune system, induction of cancer, muscle atrophy, and osteoporosis is relevant for health problems on Earth as well as for long-term crewed space flight.

Furthermore, exploration demands life support systems, for which gravitational biologists take over severe parts of research by studying the physiology and performance of the biological components under altered gravity conditions. Waste management (which means biodegradation of waste into food production), closing of element cycles, as well as optimization of plant growing in

space bear new technologies for agriculture on Earth in extreme environments.

Future Directions

In recent years, research directions changed from descriptive observations to a deeper molecular understanding of the underlying mechanisms. New research directions are fostered by the availability of whole genomes and high-throughput technologies (Omics). This includes the long-term influence of altered gravity (microgravity and hypergravity) on the development of cells, animals, and plants by means of multi-generation experiments. These experiments require biological life-support systems which allow the analysis of the complex interaction of different species in artificial habitats with the direct application in the future of food production, waste removal (solid, liquid, and gaseous), and recycling. Knowing how biological systems manage the absence of gravity is mandatory for long-term orbital and interplanetary missions and will have an impact on health and plant breeding issues on Earth.

Gravitational Collapse, Planetary

Sean N. Raymond

Laboratoire d'Astrophysique de Bordeaux,
CNRS, Université de Bordeaux, Bordeaux,
France

Definition

Gravitational collapse is the collapse of a region of material under its own gravity, for example, of the dense core of an interstellar cloud on its way to becoming a star. Gravitational collapse occurs when the local self-gravity (i.e., the inward-directed force) exceeds the restoring force, which is often in the form of thermal gas pressure or turbulent stirring.

Overview

In astrophysics and planet formation, gravitational collapse is extremely important, and the process is thought to occur in a variety of settings and on a range of different size scales. For example, stars are thought to form from clumps of gas that are gravitationally unstable within ► [molecular clouds](#). In addition, an alternate to the core accretion model for giant planet formation is the top-down, disk instability model. This model proposes that giant planets may form within the very short span of a few thousand years in the outer regions of gravitationally unstable

► [protoplanetary disks](#). Finally, models for the formation of ► [planetesimals](#) suggest that they may form via the gravitational collapse of aggregates of pebble- to boulder-sized bodies that are concentrated within turbulent structures in protoplanetary disks.

Gravitational Collapse, Stellar

Steven W. Stahler
Department of Astronomy, University of California, Berkeley, CA, USA

Definition

The rapid contraction of a fluid mass because of the mutual gravitational attraction of its component particles is called gravitational collapse. If the forces supporting the object are weak, then its internal elements freely fall toward one another, leading to a highly condensed final configuration. As a consequence of the inverse-square nature of the gravitational force, the duration of collapse (known as the ► [free-fall time](#)) depends mainly on the object's initial density. In practice, only the very large masses found in astronomical bodies are susceptible to this process. Examples are

dense cores within molecular clouds, which collapse to form stars, and the interiors of massive stars, prior to supernova explosion.

Gravitational Focusing

Rory Barnes
Astronomy Department, University of Washington, Seattle, WA, USA

Definition

Gravitational focusing refers to the enhancement in the likelihood that two particles will collide, due to their mutual gravitational attraction. Without gravity, the probability of a collision scales with the cross-sectional area of the two particles, but with gravity, some particles that would have missed each other can still collide. In other words, the particles have effective cross sections larger than their physical cross sections. In the presence of only two bodies (two-body approximation), the gravitational enhancement factor is given by $1 + (v_{esc}/v_{rel})^2$, where v_{esc} is the particle's escape speed and v_{rel} is the relative velocity of the two particles. Gravitational focusing is important during planet formation, as it leads to faster growth.

Definition

The Great Chain of Being suggests that all things in existence are connected in an unbroken, hierarchical chain, from the simplest forms to the most complex ones.

Overview

A prevailing idea through the ages is that of the Great Chain of Being, understanding the universe as a hierarchy of beings, an unbroken chain of existence, from the simplest forms to the most complex ones, from non-living matter to the most rational creatures (Lovejoy 1936). In his *History of Animals* from the fourth century BCE, Aristotle arranged all beings in a ladder of nature,

a *scala naturae*, a gradation of natural things from minerals, through plants and animals, to the human being. The chain of being got biological significance with, among others, Gottfried Wilhelm Leibniz, Carl Linnaeus, Georges-Louis Leclerc de Buffon, and Charles Bonnet. Nature does not make jumps, *Natura non-facit saltus*, as Carl Linnaeus formulated it in *Philosophia Botanica* (1751). There is continuity in nature. In that respect, the Great Chain of Being is connected to the Principle of Plenitude, the fullness of being. The principle suggests that every possible form of creature exists. This could also be understood in a temporal sense that every possible form of creature, even though not existing right now, might have existed before or could be realized at some stage in the future. Continuity is an idea implicit in that of plenitude. In the early nineteenth century, this continuity of nature became understood in temporal meaning. Jean-Baptiste de Lamarck went from a static concept of the series of life-forms to a theory of species transformation that life had developed over time from simpler to more complex forms. During the nineteenth century, the Great Chain of Being was replaced by another metaphor, the Tree of Life, which also stressed on the continuity of nature, but took into account the genealogy and evolution of life-forms, as in Lamarck's *Philosophie zoologique* (1809) and Darwin's *Origin of Species* (1859).

Great Oxidation Episode

► Great Oxidation Event

Great Oxidation Event

Andrey Bekker

Department of Earth Sciences, University of California, Riverside, CA, USA

Department of Geology, University of Johannesburg, Johannesburg, South Africa

Keywords

Paleoproterozoic · Lomagundi carbon isotope excursion · Huronian glaciation · Rise of atmospheric oxygen · Great Oxidation Event · Great Oxidation Transition · Great Oxidation Episode

Synonyms

Great Oxidation Episode; Great Oxidation transition; Oxyatmversion; Rise of atmospheric oxygen

Definition

The Great Oxidation Event (GOE) refers to the transition from the mildly reducing Archean atmosphere-ocean system to the oxygenated atmosphere and shallow oceans of the early Paleoproterozoic that started at ~2.4 and ended between 2.1 and 2.0 Ga (Holland 2002). The beginning and the end of the GOE were never explicitly defined. In general terms, the beginning of the GOE is marked by the disappearance of mass-independent fractionation of S isotopes and

an increased range of mass-dependent fractionation of sulfur isotopes in association with highly variable carbon isotope record, Huronian glaciations, and the final stage in the assembly of the supercraton Superia (Bekker et al. 2004; Holland 2006; Bekker and Holland 2012; Gumsley et al. 2017). Although the term implies a relatively short duration, as that of phenomena used in event stratigraphy, the GOE is originally defined to last more than 200 Ma and finish at the end of the >2.22–2.06 Ga Lomagundi carbon isotope excursion during which between ~12 and 22 times the oxygen content of the present-day atmosphere was released to surface environments (Karhu and Holland 1996). While the internal texture of the GOE is still unresolved and remains to be a topic of further work (see Poulton et al. 2021), during these 200 Ma, atmospheric oxygen likely fluctuated across the level of 10^{-5} PAL (present atmospheric level) to a magnitude of fully oxygenated atmosphere (well below the modern level) before rapidly falling to much lower atmospheric and ocean oxygen concentrations in the immediate aftermath of the Lomagundi carbon isotope excursion (Ossa Ossa et al. 2018a). The GOE ended up with the ocean deoxygenation in association with the supercraton Superia breakup, sea-level rise, and deposition of Mn- and P-rich sediments (Bekker et al. 2003).

History

The notion that the early Earth's atmosphere did not contain oxygen is deeply rooted in studies of biology and chemistry in the eighteenth and nineteenth centuries (Priestley 1781; Phipson 1893). The first detailed discussion, founded on geological evidence that atmospheric oxygen was low and then rose in the Middle Precambrian, was presented by MacGregor (1927), a director of the Rhodesia Geological Survey, based on his observations on sedimentary successions preserved in the Archean ► [greenstone belts](#) and the Paleoproterozoic Magondi Mobile Belt of Rhodesia (Zimbabwe). This interpretation remained largely unnoticed since poor age constraints limited correlation of Precambrian sedimentary

successions, making it difficult to constrain the age and stratigraphic position of this event. By the 1960s, several independent lines of evidence were employed to provide a strong support for atmospheric oxygenation in the Middle Precambrian. S.M. Roscoe (1969, 1973) working for the Geological Survey of Canada in the Huronian basin of Southern Ontario observed that the lower part of the Huronian succession contains detrital pyrite and uraninite and reduced paleosols, while the upper part has red beds and oxidized paleosols; sandwiched between these levels, the middle part recorded three glacial events (Fig. 1). Similar rounded grains of pyrite, uraninite, and siderite (Fig. 2), which are not stable in contact with oxidized waters and

oxygenated atmosphere, were also observed worldwide in fluvial conglomerates from sedimentary successions of similar and older age (e.g., Schidlowski 1966; Rasmussen and Buick 1999). Roscoe (1973) named this transition at ~ 2.3 Ga “oxyatmoverison.” Interestingly, as shown on Fig. 1, more than 40 years later, our geochronological and stratigraphical estimates for this transition did not change significantly. Preston E. Cloud Jr. of the University of California, Los Angeles (UCLA), linked biological evolution and environmental changes suggesting that once efficient oxygen- and peroxide-mediating enzymes developed, oceans became oxygenated and banded iron formations were replaced by red beds in the rock record by ~ 1.8 – 2.0 Ga (Cloud

Great Oxidation Event, Fig. 1 Generalized stratigraphic sections of the Pilbara, Griqualand West/Transvaal and Huronian successions, highlighting the stratigraphic position of Paleoproterozoic global glaciations, C- and S-isotope chemostratigraphy, and published geochronology (after Bekker et al. 2020 and 2021 with additional information on mass-independent fractionation of sulfur (MIF-S) and mass-dependent fractionation of sulfur (MDF-S) from Poulton et al. 2021). Neither stratigraphic

thickness nor absolute age are implied by the thickness of units in stratigraphic columns, whereas gaps along stratigraphic sections are hiatuses on unconformities. Bub.lyee is the Bubbawalyee Formation; Q1, Q2, and Q3 are respectively Quartzite 1, 2, and 3; MBM is the Meteorite Bore Member. The exact stratigraphic position of the transition from MIF-S to MDF-S is uncertain for the Huronian Supergroup and therefore not shown

rounded siderite grain, with core of compositionally banded siderite and syntaxial overgrowth (From Rasmussen and Buick 1999); (c) detrital, rounded pyrite grains from the ~2.64 Ga Black Reef Quartzite, South Africa; and (d) ~2.45 Ga banded iron formation, Western Australia

1968). Heinrich D. Holland of Princeton University, on the basis of geochemical arguments and the presence of detrital uraninite in siliciclastic fluvial and shallow-marine successions, inferred the occurrence of a largely anoxic atmosphere before ~1.8 Ga (Holland 1962). These interpretations were not universally accepted and they were contested on various occasions (e.g., Dimroth and Kimberley 1976; Ohmoto 2004 and references therein). Arguments of the 1970s–1990s helped to deepen our understanding of timing and different geochemical and geological proxies for the rise of atmospheric oxygen as well as to quantify atmospheric and seawater oxygen levels implied by these proxies. Most of these arguments were

put to rest by 2000, when James Farquhar of the University of Maryland (Farquhar et al. 2000) discovered mass-independent fractionation of sulfur isotopes in Archean sedimentary sulfides and sulfates, which can only be explained by photochemical processes in the atmosphere with low levels of oxygen ($<10^{-5}$ PAL). This approach was subsequently applied to infer that the rise of atmospheric oxygen started at ~2.45 Ga (Bekker et al. 2004; Hannah et al. 2004; Guo et al. 2009; Warke et al. 2020) and that atmospheric oxygen fluctuated across the 10^{-5} PAL level until ~2.22 Ga (Poulton et al. 2021). In the last decade, a number of studies were published, which suggested transient, low-level oxygenation events

before the GOE, of either global or local extents (e.g., Anbar et al. 2007; Crowe et al. 2013; Planavsky et al. 2014). The current and future research is now faced with a challenge: how to reconcile the notion of the long-lasting (>1 Ga) period with transient or low-level oxygenation with a geologically rapid transition to the oxygenated atmosphere at ~ 2.4 Ga.

Overview

Evidence is growing for supporting oxygenic photosynthesis as early as ~ 3.0 Ga ago and for transiently, globally or locally, oxygenated environments since that time (Anbar et al. 2007; Crowe et al. 2013; Planavsky et al. 2014). However, it is clear that mass-independent fractionation of sulfur isotopes persisted in the sedimentary record until ~ 2.22 Ga, indicating that oxygen was not a stable component of the

atmosphere at concentrations higher than 10^{-5} PAL, until more than half billion years later (Farquhar et al. 2000; Bekker et al. 2004; Poulton et al. 2021) and that large-scale fluctuations in atmospheric oxygen across the 10^{-5} PAL level continued after the GOE started. This is somewhat disconcerting considering a relatively small size of atmospheric oxygen reservoir and theoretical modeling indicating bistability of oxygen in the atmosphere at either very low ($<10^{-5}$ PAL) or substantial ($>5 \times 10^{-3}$ PAL) steady-state concentrations (Goldblatt et al. 2006). The rise of atmospheric oxygen in the early Paleoproterozoic is associated with the Huronian ice ages, when the Earth experienced four, potentially low-latitude glaciations between ~ 2.45 and 2.22 Ga ago (Fig. 3; Rasmussen et al. 2013). Association between the rise of atmospheric oxygen and global glaciations in the Paleoproterozoic has been explained by high (>1000 ppm) concentrations of methane in the Archean anoxic

Great Oxidation Event, Fig. 3 Secular carbon isotope variations in seawater and redox indicators for the oxidation state of the early Paleoproterozoic atmosphere-ocean system (Modified from Bekker and Holland 2012). Four blue vertical bars mark Paleoproterozoic glacial events; the dashed secular carbon isotope curve between 2.5 and 2.22 Ga emphasizes the uncertainty in this part of the curve; the dashed bar for marine sulfate evaporites after

ca. 2.07 Ga indicates that sulfate evaporites again became rare in the Paleoproterozoic and Mesoproterozoic records after that time. Deposition of iron formations and Mn-rich deposits indicates anoxic conditions in deep-waters. While deposition of iron formations does not necessarily require atmospheric oxygen and can be mediated by anoxygenic photosynthetic bacteria, Mn oxidation requires significant levels of atmospheric oxygen (e.g., Ossa Ossa et al. 2018b)

atmosphere, contributing to greenhouse conditions (Pavlov et al. 2000). The rise of atmospheric oxygen would decrease methane residence time and its concentration in the atmosphere, resulting in loss of greenhouse conditions; the Huronian ice ages in this scenario could reflect a transition from the anoxic, methane-rich Archean atmosphere to the oxygenated atmosphere with much lower levels of methane and sufficient concentrations of CO₂ to maintain greenhouse conditions (Bekker and Kaufman 2007).

The rise of atmospheric oxygen is also associated with dramatic fluctuations, with escalating magnitudes, in biogeochemical carbon cycle following the long-term stability of the Archean carbon cycle (Fig. 3; for notation, see ► [Delta, Isotopic](#)); their development immediately before and during the Huronian ice ages argues for a dynamic state of carbon cycle. The carbon isotope values of carbonates are mostly at around +8‰ for the duration of the >2.22–2.06 Ga Lomagundi carbon isotope excursion (Bekker et al. 2003; Fig. 3). Since positive C-isotope values in carbonates are thought to reflect high relative burial rate of organic carbon, between 12 and 22 times, the present atmospheric oxygen inventory could have been released to the surface environments during the Lomagundi carbon isotope excursion (Karhu and Holland 1996), with oxidation of reduced iron and sulfur in the continental crust consuming most of it. Indeed, red beds, sulfate evaporites, and high concentrations of redox-sensitive trace metals such as U, Mo, and Re in organic-matter-rich shales appear at that time, indicating expansion of oxidized environments. The end of the Lomagundi carbon isotope excursion is bracketed between 2.11 and 2.06 Ga (Karhu and Holland 1996) and marked by deposition of organic-matter-rich shales with highly ¹³C-depleted isotope values and Mn- and P-rich sediments (Bekker et al. 2003), whereas sulfate evaporites became again scarce, and proxies for ocean oxidation state indicate expansion of anoxia at the end of the GOE (e.g., Scott et al. 2014; Ossa Ossa et al. 2018a).

The beginning of the Lomagundi carbon isotope excursion has been related to high continental nutrient (e.g., phosphorus) flux linked to acidic

groundwaters during the GOE (Konhauser et al. 2011; Bekker and Holland 2012). The high acidity in terrestrial waters was related to extensive oxidation of sulfides for the first time in Earth's history during continental weathering. Acidic conditions in continental runoff promoted dissolution of phosphates and higher P delivery to the ocean resulting in higher relative burial rate of organic carbon and associated oxygen release. Another contributing factor could have been increased seawater sulfate content, resulting in sulfurization of organic matter and higher preservation/burial of sulfurized labile organic matter (Bekker et al. 2020). The duration of the Lomagundi carbon isotope excursion is comparable to the half-life of sedimentary rocks in the continental crust suggesting that groundwater acidity could have been largely titrated by the end of the excursion. This, by itself, could have resulted in decreased nutrient flux to the ocean ending the GOE (cf., Bekker and Holland 2012). Alternatively, weathering of organic-matter-rich shales deposited during the Lomagundi carbon isotope excursion and uplifted during the ~2.1 Ga orogenic events or submarine hydrothermal activity associated with the breakup of the supercraton Superia or emplacement of Large Igneous Provinces could have contributed reduced carbon, iron, and manganese to the atmosphere-ocean system and resulted in expansion of anoxic settings (cf., Kump et al. 2011; Bekker and Holland 2012; Ossa Ossa et al. 2018a). Although it remains unclear which of these scenarios (or a combination of them) ended the GOE, the largest and longest-lived carbon isotope excursion in Earth's history ended up with the return to low-oxygen levels in the atmosphere-ocean system.

While the timing and texture of the GOE is progressively better understood (e.g., Gumsley et al., 2017; Warke et al. 2020; Poulton et al. 2021), mechanisms for delayed oxygenation remain highly speculative. The proposed diverse mechanisms can be broadly grouped into three categories relying on (1) changes in mantle properties, (2) continental crustal growth, and (3) progressive oxidation of continental or oceanic crust. Inferred changes in mantle properties, bearing on

the surface redox state, include oxidation of the mantle by crustal subduction and mantle overturn (Kump et al. 2000; Holland 2002) and progressive cooling of the upper mantle (Konhauser et al. 2009). Continental crustal growth is held responsible for sea-level fall (emergence of landmasses; Bindeman et al. 2018) and increased subaerial volcanism during the Archean to Paleoproterozoic transition (Kump and Barley 2007; Gaillard et al. 2011), which resulted in delivery of more oxidized volcanic gases with respect to predominantly submarine volcanism in the Archean. Progressive oxidation of oceanic or continental crust by either hydrogen escape from the atmosphere or oxygenic photosynthesis is inferred in a number of models to either decrease oxygen sinks in the surface environments or increase oxidation potential of volcanic gases generated via crustal subduction and recycling (Holland 2009; Claire et al. 2006; Catling et al. 2001; Kasting 2013; Zahnle et al. 2013). All these models are concerned with the changes in the size of oxygen sinks and assume that the oxygen source did not change in size since oxygenic photosynthesis evolved.

An alternative could be that oxygenic photosynthesis was limited by low continental flux of nutrients (e.g., Mo and V; important for nitrogen fixation) into the Archean ocean or high removal potential of phosphorous in ferruginous ocean with green rust, iron oxyhydroxides, iron phosphates (Stüeken et al. 2021), resulting in limited net primary productivity and organic carbon burial. This suggestion is generally dismissed since it would have significant repercussions for the biogeochemical carbon cycle, which are not apparent in the carbon isotope record of Archean carbonates (e.g., Kasting 2013). However, continental weathering of sedimentary rocks would not return buried organic carbon to biogeochemical cycling under the Archean anoxic atmosphere; rather it would be buried again as recycled organic matter with sediments. Similarly, carbon isotope mass balance requires that carbon released by dissolution of sedimentary carbonates was also excluded from biogeochemical carbon cycle to satisfy carbon isotope values of Archean carbonates near to 0‰. Consequently, carbon isotope

Great Oxidation Event, Fig. 4 Archean biogeochemical carbon cycle; fluxes for the Neoproterozoic are in 10^{12} mol/year from Bekker and Holland (2012). Isotopic composition of Archean carbonates and organic matter is based on the geological records. It is proposed that organic and carbonate carbon contents of the Archean crust have been growing, resulting in a progressively increasing subduction flux of carbon to the mantle. Both carbonate and organic carbon were recycled during continental weathering, but did not pass through biogeochemical carbon cycle due to the lack of oxygen in the Archean atmosphere and low flux of nutrients to the oceans (see text for more details)

records could be potentially consistent with limited net primary productivity and organic-carbon burial under the Archean anoxic atmosphere-ocean conditions (Fig. 4).

The critical gap in our understanding of the GOE is why it started at ~2.45 Ga. Association with the supercontinent assembly and 2.45–2.5 Ga mantle plume events has been previously recognized (e.g., Barley et al. 2005; Kump and Barley 2007), but was not satisfactorily explained. In view of the above discussed limited net primary productivity and nutrient limitation in the Archean oceans, it is worth considering enhanced continental nutrient flux under highly acidic groundwater conditions during mantle plume events, when large amounts of CO_2 and, especially, SO_2 were released to the anoxic atmosphere and precipitated as acidic aerosols on the continents. Similar scenario could potentially explain Archean transient oxidation events, but in

contrast to these short-lived events, the 2.45–2.5 Ga time interval is marked by multiple mantle plume events that affected all continents. This period was previously singled out in the Earth's history and was linked to a fundamental change in heat flux at the core-mantle boundary (Heaman 1997).

The recent model for recycling mass independently fractionated sulfur from the continental crust to the oceans allows for as much as 100 Ma delay for the disappearance of MIF-S from the sedimentary record after the GOE started (Reinhard et al. 2013). In this model, atmosphere could have had significant level of oxygen resulting in continental weathering under anoxic conditions, while seawater sulfate and sedimentary sulfur would still carry MIF. However, the relationships among the demise of MIF in the sedimentary S isotope records, evidence for atmospheric and ocean oxygenation, ice ages, and dynamic state of biogeochemical carbon cycle clearly argue against this delay (Fig. 1; see also Poulton et al. 2021; Bekker et al. 2021). As our understanding of Earth's history evolves and as we answer some of our questions, more complex puzzles surface and motivate us to search for a deeper grasp. We are reasonably certain now when the GOE happened and what were other events associated with it. The questions that we will be likely faced for another decade or two are these: Why was the GOE delayed? Why did it happen when it happened? Why biogeochemical carbon cycle did not change after the GOE? To answer these questions, a combination of theoretical modeling with field and laboratory studies will be required. The prospective of full understanding of the Earth system is as ever a tantalizing goal to reach.

Green Bacteria

Ricardo Amils
Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Synonyms

Green nonsulfur bacteria; Green sulfur bacteria

Definition

Green bacteria denote strict anoxygenic phototrophic bacteria containing chlorosomes as light-harvesting system. Chlorosomes are very efficient light-harvesting structures. This structure is a giant antenna in which bacteriochlorophyll molecules are not bound to proteins and functions instead like a solid-state circuit. Chlorosome bacteriochlorophylls absorb light and transfer the energy to the bacteriochlorophyll located in the reaction center on the cytoplasmatic membrane. This arrangement is highly efficient for absorbing light at low intensities. Chlorosomes allow green bacteria to grow at the lowest light intensities of all known phototrophs. The green photosynthetic bacteria are divided into two distinct phylogenetic groups: the green sulfur bacteria and the green nonsulfur bacteria. The green sulfur bacteria utilize H_2S as an electron donor, so they can tolerate this toxic molecule. Most of the species are photoheterotrophs so they can assimilate few organic compounds as carbon sources. The autotrophic species of this phylum use the reverse citric cycle to fix CO_2 . The green nonsulfur bacteria only tolerate low concentrations of H_2S . Although the few species known have a chlorosome structure, their reaction center differs from the green sulfur bacteria and is more similar to the reaction center of the purple phototrophic bacteria (*Proteobacteria*). The strict autotrophic species of the green nonsulfur bacteria use the hydroxypropionate pathway to fix CO_2 , which is unique to other phylogenically ancient organisms.

Greenhouse Effect

Lisa Kaltenegger
Cornell University, Ithaca, NY, USA

Definition

The warming of a planet by the “greenhouse effect” is caused by atmospheric gases that are very efficient absorbers in the infrared but not in the visible. Symmetric, nonpolar molecules such as H₂, N₂, and O₂ have no electric dipole and cannot absorb or emit photons. They are therefore not greenhouse gases. The visible light of the parent star reaches and heats the planetary surface and is reemitted in the infrared, where part of the energy is absorbed by the atmospheric greenhouse gases with some radiated back toward the surface. Water, carbon dioxide, and methane are the greenhouse gases that raise the surface temperature on Earth to an average of +15 °C instead of −17 °C. The “runaway greenhouse” occurs when greenhouse conditions vaporize part of a water reservoir, the resulting water vapor increases the greenhouse effect, and this feedback cycle leads to loss of the entire surface water and, as a secondary effect, to the photodissociation of the atmospheric water vapor and the loss of hydrogen to space (e.g., a possible scenario for Venus, if it had a similar water reservoir as the Earth).

Greenschist Facies

Nicholas Arndt
ISTerre, University Grenoble Alpes, Grenoble, France

Definition

Greenschist facies is one of the major subdivisions of the classification scheme of metamorphic rocks. Greenschist facies refers to rocks which were affected by low- to medium-grade metamorphic conditions corresponding to temperatures of about 300–500 °C and pressures of 3–20 kbar, conditions equivalent to crustal depths of about 8–50 km. The name is derived from the green color of its characteristic minerals (chlorite) and the schistose fabric, consisting of thin and abundant layers of minerals that are naturally flat or long (foliation). This fabric is induced by recrystallization and deformation. Characteristic minerals are chlorite, actinolite, and albite ± epidote in metabasalt; chlorite, serpentine ± talc, tremolite, and brucite in meta-ultramafic rocks; and muscovite, garnet, and andalusite in metapelitic sediments. Greenschist facies prevails in the middle levels of oceanic crust and in the upper levels of orogenic belts. Many supracrustal rocks in Archean terranes are metamorphosed at greenschist facies, hence the name “greenstone belts.”

Greenstone Belt

Nicholas Arndt

Maison des Géosciences, LGCA, Université
J. Fourier, St-Martin d'Hères, France

Definition

A greenstone belt is a usually elongate structure composed dominantly of metamorphosed supra-crustal rocks (rocks formed at or near the Earth's surface, i.e., volcanics and sediments). Together with granite and gneiss, greenstone belts are the main constituents of Archean and Proterozoic cratons.

The volcanic rocks range in composition from komatiite to rhyolite but are dominated by basalt; sedimentary rock types are diverse and include shale, siltstone, sandstone, conglomerate, rare carbonates and evaporites, and (bio)chemical precipitates such as banded-iron formation and chert. The elongated shape and the vertical structures of greenstone belts are generally considered as the result of sagduction mechanisms.

The geochemical composition of the basaltic rocks shows that some formed as oceanic crust, perhaps as part of oceanic plateaus, and that others formed in island arcs. The sedimentary rocks usually document the evolution of greenstone belts from deep marine, open-oceanic settings through marginal basins filled with voluminous turbidites and chemical sediments. Very few greenstone belts include a sedimentary cap of shallow-water and quartz-rich sediments.

Although the metamorphic grade of most greenstone belts ranges from sub-greenschist to amphibolite facies, greenschist-facies metamorphism dominates. Metamorphic grade typically increases toward the plutonic or gneiss terranes bordering the greenstone belts and toward internal ductile shear zones. Abundant chlorite and actinolite in greenschist-facies basalts and serpentinite formed from ultramafic rocks impart a green color that gives rise to the name.

Because greenstone belts can be considered the down-sagged "keels" of deformed sedimentary basins, most units in greenstone belts dip steeply, are tightly folded, and are cut in places by large shear zones. These developed as parts or all of the volcano-sedimentary sequence were accreted to a continent or deformed in a continental collision zone.

Archean greenstone belts represent the oldest record of Earth's surface conditions, including the evolution and spreading of life on Earth. They host important ore deposits of metals such as gold, Cu-Zn, Ni, and Fe. Well-known examples include the Abitibi and Flin Flon belts in Canada, the Norseman-Wiluna belt in Australia, and the Barberton, Sutherland, and Murchison belts in South Africa.

Guanine

Shin Miyakawa
Kamagaya, Chiba, Japan

Definition

C₅H₅N₅O. MW: 151.13. Guanine is one of four nucleic acid bases found in DNA and ▶ [RNA](#). In double-stranded DNA, guanine base pairs with cytosine. It is hydrolyzed to xanthine. The half-life to hydrolysis in solution is 0.8 years at 100 °C and 1.3×10^6 years at 0 °C at pH 7. It has a UV absorption maximum at 246 and 276 nm (pH 7). It has been found in the Murchison meteorite and can be synthesized in HCN polymerizations, Fischer-Tropsch type reactions, and electric discharges acting on gas mixtures such as CO-N₂-H₂O.

Gullies

Ernst Hauber
Deutsches Zentrum für Luft- und Raumfahrt
(DLR) e.V., Institut für Planetenforschung,
Berlin, Germany

Keywords

Erosion · Flooding · Groundwater · Ice · Water

Definition

On Earth, the term gully refers to a small and narrow but relatively deeply incised stream course. On ▶ [Mars](#), the term is used somewhat differently to denote a landform consisting of – from top to bottom – (1) a catchment area or erosional alcove, (2) one or several transport channels, and (3) a depositional fan or apron.

Overview

Gullies were first unambiguously identified on Mars in images taken by the Mars Orbiter Camera (MOC) (Malin and Edgett 2000). Gullies are relatively small landforms, with common lengths of a few kilometers only. Close morphological analogues to Martian gullies exist in the Arctic regions on Earth (e.g., Greenland, Svalbard), but also in hot arid environments. On Earth, gullies typically form by the action of liquid ▶ [water](#). The gullies on Mars are very young and could have formed in the past several million years or even more recently (Reiss et al. 2004). Most of the gullies have been found in midlatitudes, where liquid surface water is physically not stable with the current Martian climate. Most of the present-day activity in gullies appears to be by mass wasting associated with CO₂ frost/ice (Dundas et al. 2012). Many hypotheses have been put forward to solve this conundrum, including a formation by groundwater (Malin and Edgett 2000), liquid CO₂ (Musselwhite et al. 2001), or dry granular flows (Treiman 2003). While these models avoid the problem of forming midlatitude liquid

surface water in the recent past, they have been challenged on the basis of physical and morphological arguments (e.g., see the discussion in Dickson and Head 2009). On the other hand, scenarios involving liquid water as a result of near-surface ground ice or snow melting (Costard et al. 2002; Christensen 2003) would imply precipitation (most probably snow) and, therefore, a recent climate change on Mars. The climate of Mars is susceptible to astronomical forcing (i.e., the effect on climate of changes in the tilt of the rotational axis of a ► [planet](#) and of orbital parameters such as ► [eccentricity](#)) (Jakosky et al. 1995), and it is plausible that periodic variations of the obliquity of the planet's spin axis in the past 10^5 – 10^6 years (Laskar et al. 2004) allowed the deposition of snow and ice in midlatitudes (Mischna et al. 2003). The possible existence of liquid water or water ice at or near the surface classifies some gullies as potential special regions that are banned from being investigated in situ due to ► [planetary protection](#) rules.

Gunflint Formation · Microfossils · Rove formation · Stromatolites · Sudbury impact · Traces of life

Definition

The Gunflint Formation of the late Paleoproterozoic Animiki Group comprises chemical, clastic, and volcanoclastic sedimentary rocks that are 100–160 m thick and which extend for 175 km along the Gunflint Range from northeastern Minnesota to the Thunder Bay area of Ontario, Canada. The Gunflint Formation is known for the occurrence of various ► [microfossils](#), including *Gunflintia*, *Huroniospora*, and *Eoastrian* (e.g., Tyler and Barghoorn 1954; Awramik and

Barghoorn 1977). Fossilized primitive fauna in Gunflint Formation is one of the best preserved in the geological record. For this reason, the biogenicity of older microfossils and dubiofossils is often tested by comparison with the Gunflint Formation fossil record.

Overview

The Gunflint Formation was deposited on an Archean basement at the southwestern margin of the Superior Province (see ► [“Canadian Precambrian Shield”](#)). The occurrence of granular peloidal and oolitic iron formations or taconite (an iron-bearing, high-silica, chert-like rock) characterizes the Gunflint Formation. Previous investigators subdivided the Gunflint Formation into two members based on their respective lithologies (Fralick and Barrett 1995). The lower member typically has a basal conglomerate with algal chert, covered by cherty calcareous rocks, changing into jaspilitic grainstone facies (see ► [“Jaspilite”](#)). The upper member has a stratigraphy resembling that of the lower member: algal chert is followed by a succession of cherty calcareous rocks and banded chert carbonate that passes westward into jaspilitic facies. Those facies suggest that the sediments of the Gunflint Formation were deposited under wave-dominated and tide-dominated inter-shelf environments (Fralick and Barrett 1995). The carbonaceous shales of the Rove Formation overlie the upper member of the Gunflint Formation. The occurrence of various microfossils and ► [stromatolites](#) together with kerogenous sediments makes the Gunflint and Rove Formations attractive for astrobiologists to constrain the course of the Paleoproterozoic ecological evolution (Tyler and Barghoorn 1954). Accretionary lapilli were reported from near the Gunflint-Rove boundary. These accretionary lapilli are often interpreted as impact-related ► [ejecta](#) (Addison et al. 2005). Such occurrence of accretionary lapilli creates another research interest for astrobiologists, related to whether or not a Paleoproterozoic meteoritic impact might have affected the microbial ecosystem.

Basic Methodology

The morphology of the microfossils in the Gunflint Formation can be identified and classified based on microscopic observations of multiple of thin sections. Individual microfossils were often extracted from rock chips by the maceration method to examine their morphologies. The detailed textures or morphologies of individual microfossils are observed by the secondary electron microscopy (SEM). Stable carbon isotope compositions of organic matter can be analyzed either by the standard gas mass spectroscopy or secondary ionization mass spectroscopy (SIMS). The carbon isotope compositions are expressed as the delta notation ($\delta^{13}\text{C}$) compared to the international reference of V-PDB (Vienna Pee Dee Belemnite).

Key Research Findings

A Redox-Sensitive Ecosystem

Banded iron formations (BIFs) disappeared after ca. 1.7 Ga. The BIFs of the Gunflint Formation are thus among the most recent BIFs on Earth. It is generally accepted that hydrothermal vent waters were the dominant source of dissolved iron to form BIFs. The deep ocean becomes ferruginous by an enhanced hydrothermal Fe flux, leading to Fe-rich deep-water upwelling onto oxidized shelves. Previous studies also indicate the presence of stratified ocean to form BIFs during deposition of the Gunflint Formation. Large quantities of carbon isotope compositions of organic matter and kerogen are available for the Gunflint and Rove Formations (Strauss and Moore 1992). Most organic matter has $\delta^{13}\text{C}_{\text{(PDB)}}$ values of -36 to -31‰ (Fig. 1). Such values are consistent with carbon fixation via the Calvin cycle. They are therefore consistent with earlier studies that assigned some of the Gunflint microfossils to the ► [cyanobacteria](#) phyla based on their morphology (Barghoorn and Tyler 1965). Therefore, it appears certain that oxygenic environments were widespread on the surface of the Gunflint Ocean as supported by the occurrence of banded iron formations.

Gunflint Formation, Fig. 1 Carbon isotope compositions of organic matter and kerogen in Gunflint and Rove Formations

Siliceous stromatolites in the Gunflint Formation contain abundant microfossils and hematite. Current Fe-isotope studies of hematite suggest that such siliceous stromatolites formed in low oxygen conditions or near the redoxcline (Marine-Carbonne et al. 2011). This engenders the possibility that a redoxcline was present at shallow water depth, implying that reducing environments were more widespread among surface areas than was previously thought. The Fe-isotope studies suggest that chemoautotrophic iron-oxidizing microbial ecosystems are potential primary producers at around the redoxcline. Such geochemical data are consistent with some paleontological observations (Knoll 2003).

Disagreement persists among researchers (1) whether cyanobacteria were the major primary producers and (2) how deep the oxygenated waters developed. Chemoautotrophic Fe-oxidizing bacteria might be the alternative primary producers to cyanobacteria (Planavsky et al. 2009). On the other hand, the activity of chemoautotrophic Fe-oxidizing bacteria is dependent on cyanobacterial activity because of their

necessity of dissolved O_2 , which further suggests that biomass production of chemoautotrophic Fe-oxidizing bacteria cannot exceed that of cyanobacteria. Black shales of the Rove Formation are rich in organic carbon (up to 6 wt%), suggesting high microbial productivity during sedimentation. The absence of hematite deposition implies less influence of chemoautotrophic Fe-oxidizing bacteria in the Rove Formation than in Gunflint. In this situation, cyanobacteria are the only reliable primary producers. ► Carbon isotope compositions of organic matter of the Rove Formation are compared to those of the Gunflint Formation (Fig. 1). It is noteworthy that no carbon isotope difference was found between organic matter of the Rove and Gunflint Formations, which suggests that the dominant primary producers for both formations were most likely cyanobacteria.

Ion microprobe analyses were also performed on individual microfossils and microscale organic matter (House et al. 2000; Ishida et al. 2018). The Gunflint microfossils analyzed using an ion microprobe show a range of $\delta^{13}\text{C}_{\text{(PDB)}}$ values

Gunflint Formation,**Fig. 2** Accretionary lapilli in Gunflint Formation

of -45 to -32% . Extremely ^{13}C -depleted compositions down to -45% were not consistent with carbon fixation via the Calvin cycle, and they were explained by involvement of methanogens and methanotrophs in the ecosystem (House et al. 2000). On the other hand, such ^{13}C -depleted values were found only in micro-scale analysis implying that activities of methanogens and methanotrophs were limited in space. Therefore, the possibility exists that ^{13}C -depleted organic matter and heavy Fe-isotope in hematite might represent local environmental effects rather than widespread characteristics in the surface ocean. Nitrogen isotope compositions or organic matter were analyzed by ion-microprobe or stepwise combustion methods (Ishida et al. 2012, 2017, 2018). $\delta^{15}\text{N}_{(\text{air})}$ values of organic matter, ranged from $+2.9$ to $+8.0\%$, are within a reasonable range explained by the N_2 -fixation by cyanobacteria and biological nitrogen recycling under the oxic condition. Sedimentary organic matter in the Gunflint Formation generated large quantities of petroleum (Rasmussen and Muhling 2019). Those petroleum were migrated and disseminated in the Gunflint Formation, although the timing of petroleum generation is still uncertain.

Sudbury Impact Record

The Sudbury Structure in Ontario (Canada) was most likely generated by a hypervelocity impact at 1850 ± 1 Ma. Previous investigators searched for “evidence” of the Sudbury impact in the Gunflint Formation. The potential impact-related bed appears in the recrystallized and silicified carbonate sequence in the uppermost Gunflint Formation. The proposed ejecta layer ranges from a few tens of centimeters thick (Fig. 2). Accretionary lapilli appear near the middle of this specific layer. They are considered as ejecta products. Planar deformation features (PDFs) were also found in quartz and feldspar grains. Most grains with PDFs are located within accretionary lapilli. Tsunami-like deposits, associated with tektite and glassy materials, also appear at the top of the Gunflint Formation, for which the depositional age is consistent with the time of the Sudbury impact (Addison et al. 2005). Those features suggest that the Sudbury impact event was most likely recorded in the Gunflint Formation and that accretionary lapilli might represent impact ejecta, although the alternative origins, such as volcanic ashes, are not excluded (Schumacher and Schmincke 1995; Addison et al. 2010). Earlier reports described the difference

between the fossil-rich Gunflint Formation and the fossil-absent Rove Formation and discussed the possibility of impact-induced extinction (Addison et al. 2005).

Future Directions

The late Paleoproterozoic represents a unique period in the evolution of the redox conditions of the atmosphere and oceans because very localized oxic and anoxic conditions were present. During the transition from Gunflint to Rove oceans, the deep-water conditions became Fe poor because of either euxinic or suboxic deep-water conditions (Poulton et al. 2004; Slack et al. 2007). Dynamics of redox changes and/or Fe-flux changes are important for the astrobiology community to evaluate the tolerance and/or adjustability of anaerobic microorganisms to oxic and metal-poor conditions. The Gunflint and Rove Formations will provide good opportunities to examine the survival of microbial ecosystems to impact events. Furthermore, current experiments and theoretical studies suggest that impact events can convert atmospheric CO₂ and N₂ into CH₄ and NH₃. Therefore, C and N isotope compositions of ancient kerogens might be used to evaluate the effect of an impact event on contemporary microbial ecosystem. In brief, no marked change was observed in carbon isotope compositions of organic matter from the Gunflint Formation to the Rove Formation (Fig. 1), which implies that either (1) the Sudbury impact event did not considerably affect the microbial communities or (2) the impact event affected it, but the microbial ecosystem recovered quickly enough that the influence was not recorded in rocks. To evaluate the effect in greater detail, high-resolution geochemical data will be necessary. Recent developments of analytical techniques will allow a more detailed examination of microfossils, and new data will be obtained to constrain how they lived and how they coexisted with other communities and adjusted to radically changing environments (Maldanis et al. 2020).

Definition

The Late Proterozoic ► **Gunflint Formation** comprises 100–160 m thick iron-rich chemical, clastic, and volcanoclastic sedimentary rocks

extending for 175 km along the Gunflint Range from northeastern Minnesota, USA, to the Thunder Bay area of Ontario, Canada. The iron formation is well dated at $1,878 \pm 1.3$ Ma by U-Pb on zircons (Fralick et al. 2002). The microfossil assemblage of the Gunflint Formation is renowned among astrobiologists for its excellent preservation in stromatolitic and non-stromatolitic cherts and for its abundance and diversity of filamentous, coccoidal fossils and problematic forms that are reported only in iron formations between 2.1 and 1.7 Ga.

Overview

The Paleoproterozoic (2.5–1.6 Ga) era is a crucial and unique time of changing ocean and atmosphere's chemistries. During this period, the atmosphere and surface ocean waters were likely moderately oxygenated (1–10% PAL; present atmospheric level of oxygen). Traces of this changing redox conditions are globally detected in the geological record since the GOE (Great Oxidation Event, around 2.4 Ga), but local oxygenation probably occurred earlier. The deeper bottom waters might have been euxinic (anoxic and sulfidic; Canfield 1998) or only anoxic or dysoxic (i.e., having low oxygen levels between anoxic and hypoxic levels) (Johnston et al. 2009), with a transient return to a ferruginous ocean possibly around Gunflint times, at 1.9 Ga (see review in Lyons et al. 2009).

The Paleoproterozoic rocks host the oldest ► **microfossils** diagnostic of modern ► **cyanobacteria** in carbonate formations, for example, the Belcher Fm, Canada, and the Franceville Fm, Gabon (Amard and Bertrand-Safarti 1997; Hofmann 1976; review in Knoll and Golubic 1992), contemporaneous of the Gunflint Fm, and the oldest microfossils of stem-group eukaryotes, in 1.8 Ga shales from China and 1.65 Ga shales from Australia (reviews in Knoll 2003; Knoll et al. 2006). Diverse microfossils of unknown biological affinities are reported from iron formations around the world, including the Gunflint Fm. The Paleoproterozoic record of biological activities also includes ► **stromatolites** and

► **biomarkers** (discussed elsewhere in this volume), macroscopic carbonaceous compressions and possible pyritic fossils, mat rip-ups, and putative fossil or trail impressions.

Gunflint Microbiota

The stromatolitic and nonstromatolitic cherts of the Gunflint Formation have been first investigated in the classical work of Barghoorn and Tyler (1965), Awramik and Barghorn (1977), Cloud (1965), and Strother and Tobin (1987). The stromatolites have variable chemical composition (iron rich, siliceous, calcitic) and morphologies (from small – sometimes branching – centimeter-scale columns to large domes up to 1 m in diameter) (Planavsky et al. 2009). The assemblage includes prokaryotic taxa difficult to relate to extant organisms. No eukaryotes are unambiguously recognized, although some taxa found in nonstromatolitic cherts like *Eosphaera* (vesicles surrounded by a layer of smaller coccoids in an envelope) and *Leptotrichos* (5–30 μm solitary coccoids) could be prokaryotic or eukaryotic (Knoll 1996). In the stromatolitic cherts (Fig. 1), the assemblage contains star-like forms (*Eoastrion*), coccoids (*Hurioniospora*), problematic forms (*Kakabekia umbellata*), filaments (*Gunflintia*), and budding tubular forms (*Archaeorestis*). *Gunflintia* filaments are coated by iron oxides and have been compared to modern iron bacteria *Leptothrix* (Knoll and Simonson 1981), and geochemical analyses have evidenced the activities of Fe-oxidizing bacteria (Planavsky

et al. 2009). *Gunflintia* and *Hurioniospora* can also be preserved by pyrite, some fossils showing the presence of small hollow, sometimes C-filled vesicles interpreted as cells of heterotrophs degrading them (Wacey et al. 2013). In situ sulfur isotope analyses of individual microfossils showed that pyritization resulted from the activity of sulfate-reducing bacteria within anoxic, sulfate-poor sediment pore waters (Wacey et al. 2013). Carbon isotopic analyses performed on individual Gunflint microfossils (*Gunflintia* and *Hurioniospora*) (House et al. 2000) showed $\delta^{13}\text{C}$ values of –31‰ to –37‰ consistent with carbon fixation via the Calvin cycle, except for two badly preserved specimens of *Hurioniospora* which had extremely ^{13}C -depleted compositions down to –45‰. Most microfossils do not show a preferred orientation and are probably planktonic, but *Gunflintia* filaments are sometimes densely intertwined and coat convex surfaces, suggesting benthic lifestyle (Hofmann 1969; Strother and Tobin 1987).

Similar associations are known in the coeval Franceville biota, Gabon (Amard and Bertrand-Sarfati 1997); the Balbirini Dolomite, Australia (Oehler 1977); the 1.8 Ga Duck Creek Dolomite, Western Australia (Knoll and Barghoorn 1976; Knoll et al. 1988); the Tyler Fm, Michigan (Cloud and Morrison 1980); the 1.7 Ga Frere Fm, Australia (Walter et al. 1976); and in other coeval iron formations and subtidal carbonates worldwide. These assemblages were widely distributed in shallow habitats where iron-rich deep waters mixed with oxygenated surface waters,

Gunflint Microbiota, Fig. 1 Gunflint microfossils in thin section through stromatolitic chert. (Pictures courtesy of K. Lepot), showing in (a) thin filamentous sheaths *Gunflintia* and coccoids; (b) double-walled coccoids; (c)

one star-like specimen of *Eoastrion* (upper left corner), filamentous sheath *Gunflintia*, coccoidal *Hurioniospora* (bottom right corner), and two large tapering, cellular filaments of possible cyanobacteria

before the late Paleoproterozoic expansion of sulfidic subsurface waters. Recent investigations of the 1.9 Ga Gunflint Formation (Planavsky et al. 2009) and another slightly younger iron formation, the 1.8 Ga Duck Creek Formation, Western Australia (Wilson et al. 2010), confirmed previous micropaleontological investigations and provided geochemical evidence supporting the presence of iron-oxidizing bacteria in these early ecosystems.

In most Proterozoic microbial mat assemblages, empty filamentous sheaths (e.g., species of the genera *Oscillatoria*, *Siphonophycus*, *Eomycetopsis*, *Tenuofilum*, *Taeniatum*, *Gunflintia*) are abundant and range from >10 μm (or >100 μm) to <1 μm in diameter (Knoll and Golubic 1992). Because of their nondiagnostic morphology, their biological affinity is difficult to determine in the absence of paleoenvironmental interpretations or fossilized behavior. The large sheaths are possibly attributed to cyanobacteria, especially when they occur in shallow-water sediments deposited in the photic zone and when their distribution shows phototaxis (movement induced by a rapid light flashing). They could also represent *Beggiatoa*-like sulfur-oxidizing bacteria forming mats at the sediment-water interface with steep redox gradient. The narrow sheaths could also represent the remains of *Chloroflexus*-type photosynthetic bacteria or of *Leptothrix*-type iron bacteria (as for *Gunflintia minuta*, which grew in an iron-rich stromatolitic environment of the Gunflint Formation) (Knoll and Golubic 1992). Similar uncertainty applies to colonies of microfossils such as the possibly heterotrophic rod-shaped *Eosynechococcus* or the coccoidal *Myxococcoides*, in the absence of paleoenvironmental information (Knoll and Golubic 1992).

Gunflint Paleoenvironmental Conditions

Geochemical proxies combined with paleontological investigations may help to constrain the metabolisms and biological affinities of the filaments and isolated cells of the Gunflint Fm. ► **Iron isotopes** and REE (rare earth element) analyses on hematite-rich stromatolites of the Gunflint Fm permitted to suggest the presence of a shallow redoxcline in the ocean, separating fully oxygenated shallow waters from iron-rich deep

waters (Planavsky et al. 2009). In the redoxcline, microaerophilic chemolithotrophic microbial ecosystems could proliferate. Cyanobacteria lived in the surface-oxygenated waters, as suggested by paleontological investigations (review in Knoll and Golubic 1992) and C-isotope analyses (Strauss and Moore 1992), and provided dissolved oxygen used by chemoautotrophic Fe-oxidizing bacteria just below. This new model could explain the presence of cyanobacteria microfossils in some Paleoproterozoic carbonate successions and the presence of iron-coated filaments and other unusual microfossils in coeval iron-rich formations.

In shallow habitats of the Gunflint Formation, iron-rich deep waters mixed locally with oxygenated surface waters (Planavsky et al. 2009). A recent study based on S-isotopes analyses, and tectonic and sedimentologic models, suggests that the shift to sulfidic conditions in the Paleoproterozoic Animikie Basin (where the Gunflint Fm was deposited) approximately coincided with the onset of restricted circulation. Therefore, the basin may record an evolving basin with restricted water circulation and thus may not reflect the open-ocean structure and composition during the global onset of sulfidic conditions (Pufahl et al. 2010).

Further detailed studies of contemporaneous iron formations are required to clarify the global extent of the chemical stratification, changing from a redoxcline between oxygenated surface waters and iron-rich deep waters to a redoxcline between oxygenated surface waters and sulfidic deep waters in the late Paleoproterozoic when iron formations disappear, and the possible implications on ecosystem evolution. The occurrence of ferruginous waters and iron formation in younger Paleoproterozoic successions (e.g., 1.8 Ga Duck Creek Fm, Western Australia) may suggest that the Late Paleoproterozoic expansion of sulfidic subsurface waters was globally asynchronous (Wilson et al. 2010).

Future Directions

The late Paleoproterozoic represents a unique period in the evolution of the redox conditions of

the atmosphere and ocean, with locally stratified waters and the development of a redoxcline. The Gunflint Formation recorded life and fossilization processes in iron-rich oxygen-poor conditions. Study of past extremophile life and iron-rich habitats is relevant for astrobiology. Such interdisciplinary investigations, combining micropaleontology with geochemistry, sedimentology, and mineralogy, are good examples of what needs to be done to improve our understanding of past ecosystems and the characterization of traces of life.

Earth · Exoplanets · Habitability · Icy satellites · Life · Mars · Solar System

Definition

Habitability refers to the capability to sustain life or for the origin of life and its potential can be constrained to a period or a planetary environment. Basic elements to determine the potential for habitability of a member of the Solar System are: availability of liquid water, energy sources, physicochemical conditions for the origin and sustenance of life, and presence of organics. Assessment of habitability depends on the tools available to study a particular planetary body that may be: observational data from telescopes, images and data from spacecraft, terrestrial analog sites, meteorites, in situ measurements by landers and rovers, and experimental and theoretical models.

History

Venus and Mars were the first bodies in the Solar System considered habitable based on empirical evidence. Clouds on Venus were evidence of a warm and habitable climate until 1958 when radio observations pointed to a surface temperature of 600 K (Lewis 2004). Venera missions in the 1970s returned photographs and data from Venus' surface that showed a dry, hot planet with a 92 bar atmosphere where life was not possible,

but clouds were and are still considered a likely habitat for Venusian life (e.g., Morowitz and Sagan 1967; Seager et al. 2020).

During the end of the XIX century, drawings based on telescope observations portrayed lines crossing the Martian surface that were later interpreted as canals built by a civilization. As telescopes technology improved and photography were used to capture astronomical images, those lines faded as well as the idea of such civilization (Lewis 2004). Even so the idea that Mars was habitable continued, color variations in its surface were interpreted as vegetation responding to seasonal changes. In 1947, Gavriil Tikhov, a soviet scientist, funded the Sector for Astrobotany of the Kazakhstan Academy of Science to study the spectroscopic properties of plants to identify the ones that matched the spectral signatures of the Martian surface (Tejfel 2009). The work by Tikhov and his collaborators was published in a series of proceedings and the first astrobiology book (Tejfel 2009). Salisbury (1962) deduced that “earthly organisms could not account for the markings on Mars”; however, he was still supporting the idea that those markings were best explained by the presence of life. Viking mission in 1975 performed the first experiments to detect life in Martian soil without finding it (Klein 1979).

In 1983, Europa, the smallest of the Galilean satellites, became the first icy satellite included in the list of habitable worlds (Reynolds et al. 1983) as a feedback between three main findings: (1) the flybys of Voyager 2 (launched in 1977) which retrieved images showing an astonishing young Europa surface; (2) the first observations of hydrothermal communities thriving in the absence of sunlight and sustained by mantle derived fluids at the Galapagos Spreading Center in 1977 (Humphris and Klein 2018); and (3) the discovery of lakes beneath the Antarctic ice sheet, e.g., Vostok Lake, during the same decade.

The habitability of Europa is partly interchangeable to Enceladus. With the discovery of the whitish E-ring at Enceladus orbit by Walter Feibelman in 1966 it was suggested that the ring was composed of water ice originated from this satellite. However, the scarce knowledge about

the energy supplied by tidal dissipation on icy satellites at the time could not envisage a heat source, besides radioactive decay, and accretion, to justify that the E-ring was a consequence of material ejected from the active satellite (Henin 2018; Hendrix et al. 2018). Studies about the orbital properties of icy satellites and psychrophilic extremophiles performed since the end of the 1970s enriched the understanding of habitability in the Solar System bodies.

The discovery of organics in Titan's atmosphere generated by the reactions of N_2 and CH_4 led to models and experiments focused on understanding the nature of the hazes that cover the satellite. The Cassini-Huygens mission displayed a geologically complex satellite whose potential for habitability we are just starting to explore. Some authors have proposed that Titan's organic chemistry may be like Earth's conditions before the appearance of life (Raulin et al. 2010), but this view has been challenged by experimental results that show that atmospheres with CO and CO_2 – such as the one expected for prebiotic Earth – produce organic compounds different to those

produced in reduced Titan-like atmospheres (Trainer 2013). Margulis et al. (1977) analyzed the Titan habitability using extremophiles as models concluding that terrestrial organisms could hardly survive on this satellite.

Overview

The potentially habitable environments can be limited to a region or time for a given planetary body (satellite, dwarf planet, or planet). The main characteristics to assess the habitability potential of a planetary body in the Solar System are (Fig. 1):

1. Liquid water: considered the best and most abundant solvent for carbon-based life, its properties and relevance for life on Earth resulted in the strategy “Follow the water” (Mottl et al. 2007).
2. Organics: indicate the potential for the origins of life or the presence of life either in the past or present.

H

Habitability of the Solar System,

Fig. 1 Representation of the knowledge state of habitability in selected Solar System bodies. The habitability potential comprises four categories: (1) liquid water, (2) organics, (3) energy sources for life, and (4) suitable physicochemical conditions for life. Discontinuous regions represent uncertainty either for present or past conditions and the white ones lack of information or conditions for that category

3. Energy sources: organisms harvest redox reactions to promote cellular processes.
4. Physicochemical conditions for life: environmental characteristics such as the presence of bioelements (sulfur, potassium, calcium, etc.), temperature, pH, and pressure that are favorable to carbon-based life.

Basic Methodology

Assessment of habitability in the Solar System requires to identify places and times where a planetary environment was suitable for the origins or sustenance of life. The tools to constrain which elements for habitability were or are available in a Solar System body are (Fig. 2):

1. Remote observations: Telescopes and spacecraft (flybys and orbiters) provide data about the surface and atmospheric composition, global processes such as atmospheric escape, volcanism, and other characteristics like magnetic fields and presence of water. Also,
2. Robotic in situ exploration: Landers, rovers, and other robotic explorers (e.g., Dragonfly for Titan) give a closer knowledge of planetary characteristics by directly analyzing the physical and chemical properties of the subsurface, surface, and atmosphere. Along with remote observations provide constraints to the geologic history, structure of planetary bodies, and the initial properties of the Solar System.
3. Terrestrial analog sites: Sites on Earth that share chemical (e.g., pH, composition) or physical (e.g., temperature, humidity) conditions with a given environment of a Solar System planetary body. For example: hydrothermal fields, hypersaline lakes, permafrost, and experiments with extremophiles.
4. Sample return: Lunar and Martian meteorites are samples available on Earth that help to constrain the characteristics of the Moon and

Habitability of the Solar System, Fig. 2

Diagram of the main tools used in astrobiology (outer circle) to build the concepts (inner circle) required for evaluating the habitability of the Solar System

Mars, while other meteorites constrain the initial history of the Solar System. In situ analysis by robots is limited to a suite of instruments and experiments while sample return missions provide the opportunity to apply a wider variety of techniques that can reveal more details about a given planetary environment (National Academies of Sciences et al. 2018).

5. Earth's geologic history and present characteristics: As the only inhabited planet we know of, the study of the origins of life and our planet geologic changes provide the first clues to understand the characteristics of habitable environments.
6. Theoretical and experimental models: Models simulate a given set of planetary characteristics to understand the processes that lead to the origins of life, set the limits of life, and to evaluate the chemical and/or physical conditions of a present or past planetary environment, or to provide clues of the origin of the solar system and the initial water inventory.

Key Research Findings

Venus exploration is limited due to the harsh atmospheric and surface conditions; landers have not visited the planet since the 1980s and the last Venus orbiter ESA Venus Express, finished operations in 2014. In 2020, radio observations claimed the detection of phosphine (PH_3), a chemical compound that has no known source in Venus and is produced by life on Earth (Greaves et al. 2020). This claim remains under debate by the scientific community (e.g., Akins et al. 2021) and shows how much we ignore our closest neighbor planet.

Mars has been continuously visited by orbiters, landers, and rovers since 1994. In 2021, three missions are expected to study the Red Planet: Tianwen-1 (China), Hope (the United Arab Emirates), and Perseverance (the United States). Geologic evidence and in situ sample analysis have provided strong evidence of liquid water in the surface and other characteristics such as volcanic activity, chemical elements relevant for life,

and presence of organic matter that indicates that Mars was a habitable planet about 3.5 billion years ago (Cockell 2014; Eigenbrode et al. 2018).

The Galileo spacecraft (1989–2003) images of Europa captured by the Solid-State Imaging (SSI) experiments revealed surface features like lenticulae, bands, cryovolcanic structures, chaos regions, and ridges whose interpretations are consistent with a geologically active satellite (Siddiqui 2018). The uncertainty about water distribution was dissipated after the detection of inductive currents that describe a salty global ocean beneath the ice crust. More recently, a survey performed with the Hubble Space Telescope (HST) at infrared and ultraviolet has provided evidence of water vapor plumes at Europa leading hemisphere (Paganini et al. 2020). Also, the perception of the endogenous salts evolved from entirely sulfates to sulfates and chlorides (Hibbitts et al. 2019). Several answers will be provided by the NASA Europa Clipper mission (launch date 2024) and the ESA JUperiter ICy moons Explorer (JUICE) mission (launch date 2022) (Hendrix et al. 2018).

The understanding of Saturn system has several chapters of advancement thanks to Cassini spacecraft (1997–2017) and the Enceladus water plume is located among the major discoveries. Enceladus' south pole comprises extensive crater-free regions and high temperature levels, measured by the Cassini mid-IR interferometer correspond closely with the active tectonic fractures known as "tiger stripes" which may feed water plumes. The finding of silicon-rich nanometer-sized dust particles by the Cassini Cosmic Dust Analyzer (CDA) has added a hint of hydrothermal activity which was reinforced by the detection of hydrogen and hydrocarbons in the plume. The convergence of these discoveries has guided thinking about a liquid media as an energy source for chemotrophs (Waite et al. 2017; Hendrix et al. 2018).

Titan has a geologically active surface and methane lakes with ethane and other organic compounds (Henin 2018) and poses the opportunity to test liquid methane as a solvent for life under low temperature (-180°C). Acrylonitrile has been

proposed as the molecule that can build vesicles for life compartmentalization because membranes made of lipids would lose its elasticity under cryogenic temperatures (Stevenson et al. 2015). Titan's interior is potentially habitable starting from the silicate core boundary with the water mantle up to the ammonia and water ocean below the water ice crust (Norman and Fortes 2011).

Future Directions

Solar System exploration although not always focused on habitability, provides information relevant to understanding the habitability potential of the Solar System. Thus, all future missions aimed to study a member of our planetary system are relevant for the assessment of the past and present habitability of the Solar System.

Planets and satellites of the Solar System are the nearest experimental bench to explore how planets evolve and how habitability may change with time to infer the characteristics of exoplanets and constrain their habitability potential.

Definition

Habitability has been defined as “the potential of an environment (past or present) to support life of any kind” (Steele et al. 2005). Consequently, the concept of habitability depends on the conditions life requires, which commonly are described as complex chemistry taking place within a liquid solvent and with access to energy. It is reasonable to assume that putative life on Mars would be physically implemented on the basis of organic chemistry and liquid water (Benner et al. 2004).

Beyond the conceptual requirements for habitability (water, organics, energy), life can only exist in physicochemical settings (e.g., temperature, radiation, pH) that do not cause a lethal degradation of the organisms. Consequently, habitability greatly depends on the type of biochemistry, which makes it challenging to predict the physicochemical boundaries of habitability with respect to alien life of unknown molecular composition.

Although this difficulty cannot be overcome, the discovery of extremophiles over the past few decades has greatly expanded our knowledge of the range of habitable environments for “life as we know it”. Based on these known boundaries of life on Earth, it can be conservatively estimated that habitable environments on Mars are those where liquid water is stable at temperatures below ~120 °C.

Early Mars

Among the first to scientifically discuss the putative habitability of Mars was Alfred Russel Wallace (Wallace 1907). Although Wallace largely argued against Mars being habitable, high hopes for this not being the case persisted until the 1970s when the Viking landers reported Mars to be a cold desert.

Since then, Mars exploration efforts were guided by the slogan “follow the water” and yielded a profound understanding of Mars’ watery past and the current water-ice-rich cryosphere (e.g., Lasue et al. 2013). As a result of this successful search, it symbolically transitioned to “follow the habitability.” The recent discovery of clay-rich sediments at Gale Crater by the Curiosity rover suggests that these deposits formed within a shallow-water environment of neutral pH and therefore would indicate the former existence of a habitable lacustrine environment on Early Mars (Grotzinger et al. 2014).

However, the frequency, duration, and chemistry of such habitable paleoenvironments remain largely unknown, and the degree of similarity between Early Mars’ and Earth’s habitable environments continues to be debated. Furthermore, the length of time needed and exact

physicochemical conditions required for an origin of Earth-like life remain in the realm of speculation. Therefore, any estimate on the suitability of Martian paleoenvironments for an origin of life is highly speculative as well. However, even if life never originated on Mars itself, it could have been transferred from Earth to Mars through the process of ► [panspermia](#) and continued to thrive on Mars until today.

Mars Today

Although Mars might have been habitable at the surface in the past, today the Martian surface conditions (low temperatures and pressures) usually do not allow liquid water to be stable. Only at very low-lying areas (higher atmospheric pressure) and/or if the water is very saline (reduced melting point temperature) can water remain liquid at the surface today. Local melting of ground ice and the formation of cold brines are hypothesized to be responsible for the seasonal appearance of recurring slope lineae (McEwen et al. 2011). However, such environments would only be habitable for halophilic and psychrophilic organisms that are known to thrive in arctic environments on Earth. Alternatively, in the event of a large impact into water-ice-bearing terrain, crater lakes could form and be considered to represent transitional habitable surface environments (McKay and Davis 1991).

In contrast to surface environments, it could well be that putative subsurface aquifers are the largest, most stable, and longest-lasting habitable environments on Mars. Furthermore, it can be argued that if microbial life did exist on Early Mars, it is more likely that it has adapted to the deep subsurface conditions, as life has done on Earth, than it having gone extinct entirely.

Habitability, Effect of Eccentricity

Lisa Kaltenegger
Cornell University, Ithaca, NY, USA

Definition

Variations in the ► [eccentricity](#) of a planet's orbit can lead to climate changes, including possible phase transitions of liquids on a planet's surface and therefore different climate feedback mechanisms due to ► [albedo](#) changes. A more eccentric orbit both intensifies the ratio of stellar irradiation at ► [periastron](#) to that at apoastron and increases the annually averaged irradiation, proportional to $(1 - e^2)^{-1/2}$, where e is eccentricity.

Periodic oscillations of eccentricity cause oscillations of the total amount of starlight incident on a planet in each annual cycle. These oscillations depend on gravitational perturbations from other companion objects.

Habitability, Effects of Stellar Irradiation

Lisa Kaltenegger
Cornell University, Ithaca, NY, USA

Keywords

Biomarkers · Earth geological evolution of · Habitability · Biomarkers remote detectability thereof

Definition

Stellar irradiation refers in this context to the wavelength-dependent incoming flux of photons into the planetary atmosphere from the central star. This in turn will influence e.g. the planet's atmospheric photochemistry, climate, and potential biomarkers.

Overview

The range of characteristics of planets is likely to exceed our experience with the planets and

satellites in our own Solar System by far. Models of planets more massive than our Earth need to consider the changing atmosphere structure, as well as the interior structure of the planet (see, e.g., Seager et al. 2007; Valencia et al. 2006). Earthlike planets orbiting stars of different spectral type might evolve differently (Selsis 2000; Segura et al. 2003, 2005). Modeling these influences will help to optimize the design of the proposed instruments to search for Earthlike planets. The spectral resolution required for optimal detection of habitability and biosignatures has to be able to detect those features for different stellar types as well as over the evolution of a planet (► [Biomarkers](#), ► [Spectral](#); Biomarkers, Atmospheric; ► [Habitable Planet](#), Characterization). Using a numerical code that simulates the photochemistry of a wide range of planetary atmospheres, several groups (Selsis 2000; Segura et al. 2003, 2005; Grenfell et al. 2007) have simulated a replica of our planet orbiting different types of star: an F-type star (more massive and hotter than the Sun) and a K-type star (smaller and cooler than the Sun). The models assume the same background composition of the atmosphere as well as the strength of biogenic sources. A planet orbiting a K star has a thin O₃ layer, compared to Earth's, but still exhibits a deep O₃ absorption at ultraviolet (UV) wavelengths: indeed, the low UV flux is absorbed at lower altitudes than on Earth, which results in a less efficient warming (because of the higher heat capacity of the dense atmospheric layers). Therefore, the ozone layer is much colder than the surface, and this temperature contrast produces a strong feature in the thermal emission. The process works the other way around in the case of an F-type host star. Here, the ozone layer is denser and warmer than the terrestrial one, exhibiting temperatures about as high as the surface temperature. Thus, the resulting low-temperature contrast produces only a weak and barely detectable feature in the infrared spectrum. This comparison shows that planets orbiting G- (solar) and K-type stars may be better candidates for the search for the O₃ signature than planets orbiting F-type stars. This result is promising, since G- and K-type stars are much more

numerous than F-type stars, the latter being rare and affected by a short lifetime (less than 1 Gyr).

Habitable · Habitable zone · Life · Atmospheric

Definition

“Habitability” is classically defined as the (past or present) existence of surface conditions that support life. This in turn leads to the requirement for the presence of liquid water, which is needed by all known life. “Atmosphere” refers to the envelope of gas trapped within a planet’s gravitational field and for a terrestrial planet extends from the surface up to the exosphere. This entry discusses the critical importance of atmospheres for habitability.

Overview

“Habitable” is derived from the Latin *habitabilis* meaning “to inhabit.” “Habitable” denotes environmental conditions that could support life (Steele et al. 2005) but does not necessarily imply that life is present. In simple terms one can imagine a house that is habitable but may be unlivable in. In its simplest terms habitability is classically defined as the requirement for liquid water. However, “conditions which could support

life” can be rather many more and varied. Broadly speaking, one can define three central criteria, namely, the access to (i) energy, (ii) a suitable solvent (e.g., water), and (iii) molecular complexity (e.g., via carbon chain molecules). Other factors such as the availability of nutrients and protected conditions (e.g., shelter from UV, cosmic rays, climate excesses, strong impacts, etc.) also play a role. The distribution of habitability in the Universe depends, therefore, on how well we understand the limits and occurrences of these various criteria and on how sensitively life responds to them. In this entry we will focus on the central role for habitability played by planetary atmospheres in and beyond the Solar System.

Atmospheres are essential for habitable conditions for several reasons. First, liquid water (needed for habitability) is thermodynamically unstable at low pressures. Second, (in addition to a magnetosphere) atmospheres protect the planetary surface, e.g., from harmful radiation and cosmic rays. Third, atmospheres transport heat from warm to cool regions, which helps to maintain stable conditions favored by life. Fourth, atmospheres may interact with biological and geochemical processes via feedback cycles such as the “carbonate-silicate” cycle, which stabilizes the (Earth’s) climate. Fifth, (on Earth) the atmosphere supplies CO₂ for autotrophic life and O₂ needed for aerobic respiration and hence directly supports higher life on our planet. Finally, atmospheric spectral signatures on rocky exoplanets may provide indications of surface habitability and even biosignature signals.

Key Research Findings

Huang (1960) investigated the key requirements a star should meet to maintain life in its habitable zone (HZ). Dole (1964) introduced the “complex life habitable zone (HZ)” – the region where a planet could have surface temperatures between 0 and 30 °C (for >10 % of its surface with an oxygen (O₂)-rich atmosphere and <1.5 Earth gravity). Early climate modeling by Hart (1978) suggested a narrow HZ from 0.95 to 1.01

astronomical units (AU) for a solar-type star. Kasting et al. (1988) subsequently suggested that including negative (i.e., opposing the original change) feedback mechanisms such as the carbonate-silicate cycle could significantly expand the HZ. Kasting et al. (1993) calculated the HZ boundaries for different main sequence stars.

Modern Solar System

The (classical) HZ in the Solar System lies somewhere between Venus and Mars. There are two HZ inner boundaries that may be defined. Firstly, the “water loss limit” (~ 0.95 AU, Kasting et al. 1993) occurs where a planet would lose its mass of ocean within its current lifetime due to atmospheric escape. Secondly, the “runaway greenhouse limit” (~ 0.84 AU, Kasting et al. 1993) occurs where the planetary surface temperature exceeds the critical point of water. Atmospheric clouds if present could strongly influence the HZ boundaries. Kitzmann et al. (2010) investigated the radiative effects of clouds upon atmospheric temperature for Earth-like planets orbiting F, G, and K stars. Results suggest that cloud type and altitude could significantly impact surface temperature. The HZ limits, as estimated from numerical model studies, also depend on, e.g., planetary mass, density, and atmospheric mass and composition.

Regarding the *inner* HZ, Abe et al. (2011) varied ocean mass and calculated the effect on the inner HZ boundary. Applying an atmospheric column model, Kopparapu et al. (2013) suggest that using updated water absorption coefficients and applying the same approach as in Kasting et al. (1993) lead to the inner HZ moving out to 0.99 AU.

Regarding the *outer* HZ, here, CO₂ clouds could form in the atmosphere although their radiative properties are challenging to estimate since, e.g., their shapes and sizes are not well defined. The “maximum greenhouse effect” is defined to occur at the furthest distance of planet to star for which a planetary surface temperature of 273 K

can be held for a planet having a cloud-free, CO₂ atmosphere.

Atmospheric Evolution

The solar neighborhood includes some rather young stars (e.g., Woolley et al. 1970), which could have planets resembling the early Earth in age. The Earth’s atmosphere has changed significantly over geological time. The above has motivated studying the early Earth in an exoplanetary context. For example, Grenfell et al. (2011) investigated different epochs of hypothetical Earth-like exoplanets. The Sun’s net luminosity was (20–30%) weaker on the early Earth (~ 2.5 – 4.0 Gyrs ago) compared with the modern Earth. Although observations from ancient soils (paleosols) suggest the presence of liquid water on early Earth, numerous climate model studies (see, e.g., Kasting et al. 1988) imply a completely frozen planet – the so-called Snowball Earth. The contradiction between paleosol data and model predictions is named “the faint young Sun problem.” Several possible solutions have been put forward, e.g., supplying additional greenhouse gases such as methane (CH₄) or nitrous oxide (N₂O) (Grenfell et al. 2011) to the early Earth atmosphere. Goldblatt et al. (2009) suggested a stronger greenhouse effect on early Earth due to enhanced atmospheric N₂ (considering up to three times the modern value). Greenhouse warming on early Earth is also expected to be sensitive to surface pressure (P₀). Som et al. (2012) suggested that early Earth featured (P₀ < 2) bars, based on fossilized mud droplet data.

Early Venus and Mars

How early Venus’ atmosphere evolved, whether/for how long the surface was habitable, and how it finally diverged into its modern extreme state are critical questions to address. On Mars, observed surface flow features suggest that liquid water likely existed early in its history. Analogous to the early Earth, there are difficulties for numerical studies to

reproduce sufficiently warm surface temperatures. The study by von Paris et al. (2013) suggested that including pressure broadening (which enhanced the atmospheric greenhouse effect) of N_2 can help address this issue. How the Martian atmosphere developed from possible habitable conditions to its modern-day state is challenging for interior, atmospheric, and impact models. Clearly, understanding the developments of Venus and Mars will provide useful insights for understanding the HZ boundaries around different stars.

Beyond the Solar System

Recent works have expanded the parameter range with the aim of determining which are the key factors affecting the atmospheric habitability of Earth-like planets beyond the Solar System. Factors investigated include, e.g., climate feedbacks, interactive atmospheric climate chemistry (e.g., Segura et al. 2003; Grenfell et al. 2007), radiative effects of clouds (Kitzmann et al. 2013), planetary orbit (e.g., Williams and Pollard 2003), studies of climate evolution (e.g., Selsis et al. 2007), and (of particular interest) planetary mass (see ► “Super-Earths” below) and ocean mass (Abe et al. 2011).

Super-Earths

These objects (with mass M such that $M_{\text{Earth}} < M < 10 M_{\text{Earth}}$) are already starting to be found in the HZ (see below). There exists a lively discussion as to their ability to maintain plate tectonics (e.g., Noack and Breuer 2013), which would favor habitability and affects atmospheric mass and composition via outgassing. The enhanced planetary mass of super-Earths favors slower thermal escape of the original (proto) H_2 -rich atmosphere. For example, Pierrehumbert and Gaidos (2011) suggested that collision-induced greenhouse warming of high pressure (~ 40 bar) H_2 protoatmospheres (which may be relevant for super-Earths) could also lead to a significant increase of the outward HZ boundary – maybe to as far as 10 AU for solar-like stars.

Waterworlds and Desertworlds

“Waterworld” here refers to a terrestrial exoplanet with complete ocean coverage, i.e., without exposed surface continents. “Desertworld” here refers to a terrestrial exoplanet whose surface lacks large-scale oceans and vegetation. On waterworlds, it is currently unclear whether stabilizing climate cycles, i.e., analogous to the carbonate-silicate cycle on Earth, could operate. More work on, e.g., seafloor carbonization and its dependence on, e.g., pressure, pH, etc., are required (see, e.g., Wordsworth and Pierrehumbert 2013). Regarding desertworlds, additional work estimating, e.g., the dependence of ocean mass (e.g., including the lower limit) on, e.g., plate tectonics and habitability would be useful.

Earth-Like Planets Orbiting M Dwarf Stars

These are favored targets for exoplanet search missions. Such objects are already starting to be found in the HZ. Scalo et al. (2007) provide a detailed review of habitability issues. The HZ is rather close to the star (typically ~ 0.2 AU) so that Earth-like exoplanets could be tidally locked, slow rotators. The 3D modeling study of Joshi (2003) suggested that atmospheres of such worlds could effectively transport heat from the dayside to the nightside, hence maintaining habitable conditions. Joshi and Haberle (2012) suggested that including the spectral dependence of the snow-ice albedo for modeled planets orbiting red dwarf stars led to an increase in the outer HZ by up to 30% due to a weaker snow-ice albedo feedback. Shields et al. (2013) investigated similar effects, finding that Earth-like planets in the HZ of M stars could withstand a reduction of up to $\sim 19\%$ in incoming insolation without “going snowball” – partly because of the weaker ice-albedo feedback. Kite et al. (2011) modeled potentially destabilizing (negative) climate feedbacks involving weathering and pressure on tidally locked planets. Decreasing dayside pressure led to a

warming (air is less efficiently transported to the nightside) which in turn led to a faster weathering rate, which further decreases the atmospheric pressure. Leconte et al. (2013) studied (near) tidally locked planets close to the inner HZ boundary and discussed two opposing 3D effects – firstly, water evaporated on the dayside (suggesting a runaway climate effect) but secondly, water froze out on the nightside (opposing the runaway effect). Yang et al. (2013) analyzed a cloud feedback mechanism in their 3D model study, which increased the planetary albedo and hence expanded the inner HZ boundary toward the host star for Earth-like planets orbiting M dwarf stars. A recent highlight is, e.g., planetary studies of the GJ-667 system (e.g., Anglada-Escudé et al. 2013). Finally, the recent Kepler results are starting to suggest that planets in the HZ could be quite common.

Although Earth-like planets in the HZ of M dwarfs are in some ways favored objects, there are nevertheless some aspects that could oppose the habitability of rocky planets orbiting in the HZ of M dwarf stars. Lammer et al. (2007), for example, suggested efficient escape of even hundreds of bars of CO₂ or/and N₂ atmospheres due to nonthermal escape processes for planets in the close-in HZ of M dwarf stars especially during extended early, active stellar phases – this aspect needs further investigation. Also, possibly weak (or even absent) magnetospheres for Earth-like planets in the HZ of M dwarf stars could result in strong bombardment of the planetary atmosphere by stellar and galactic cosmic rays. Associated climate and photochemical effects have been discussed by, e.g., Grenfell et al. (2012, 2013) and Segura et al. (2010).

Atmospheric Habitability of K and F Stars

K stars are also favored targets for exoplanet search missions, being rather cool, but unlike the case of the M dwarfs, planets in their HZs are unlikely to be tidally locked. Segura et al. (2003) and Grenfell et al. (2007) modeled the climate and

photochemistry of Earth-like planets in the HZ of K and F stars and showed the importance of coupling climate and photochemistry when calculating biosignature abundances. For example, they showed that key bioindicators such as O₃ and important greenhouse gases such as CH₄ respond sensitively to the stellar input spectrum and the planet's position in the HZ. The 3D study of Godolt (2012) discussed a climate feedback, which could warm (cool) the atmospheres of Earth-like planets orbiting in the HZ of K stars (F stars) – they found that enhanced (suppressed) incoming longwave infrared radiation for the M dwarf star scenario favors stronger (weaker) planetary atmospheric heating, and the effect is strengthened by enhanced (decreased) water vapor evaporation and a stimulated (suppressed) hydrological cycle. Additional exoplanets orbiting K stars, which could be habitable, are recently emerging, e.g., HD85512b (Pepe et al. 2011).

Habitability Beyond the Classical HZ

The main motivation here is to estimate how common is habitability (in all its possible forms) in the Universe. Most studies to date have focused on the Earth (“what we know”). On the other hand, one should clearly keep an open mind on the new and exciting results to come. Beyond the classical definitions, one might include alternatives to the classical requisites of life, including energy coming, e.g., not only from main sequence stars or from white dwarf HZs which move continuously inward with time. Also, Neubauer et al. (2011) calculated the (much-expanded) HZ based on non-water solvents.

Applications

Key applications of the above theoretical studies (e.g., in an exoplanet context) are, e.g., to generate scientific debate by helping to understand the main physical responses (e.g., between atmospheric dynamics, climate and composition, and

their effect on habitability), to produce scientific databases (e.g., theoretical atmospheric spectral catalogs), which help interpret current and future-planned data, and to drive future instrumentation design by predicting the range of observed signals expected and the associated signal-to-noise ratio.

Future Directions

Theoretical studies to assess our understanding of habitability are needed now, to prepare the way for next-generation missions such as the James Webb Space Telescope (JWST) and the European Extremely Large Telescope (E-ELT), which could detect the first exoplanetary atmospheric biosignatures (although this task is very challenging).

Definition

The spectrum of a planet can contain signatures of atmospheric species, which create its spectral fingerprint. The presence and abundance of atmospheric species, in the context of the properties of the star and the planet, can elucidate the underlying physics and characterize a planetary environment. Here, we concentrate on characterizing a habitable planet and see what features might have a biological origin.

History

Sagan et al. (1993) analyzed a spectrum of the Earth taken by the Galileo probe, searching for signatures of life, and concluded that the large amount of O₂ and the simultaneous presence of traces of CH₄ are strongly suggestive of biology. To characterize a planet's atmosphere and its potential habitability, we look for absorption features in the reflection and transmission spectrum of the planet. On Earth, some atmospheric species exhibiting noticeable features in the planet's spectrum result directly or indirectly from biological activity: The main ones are O₂, O₃, CH₄, and N₂O. CO₂ and H₂O are, in addition, important as ► [greenhouse](#) gases in a planet's atmosphere and potential sources for a high O₂ concentration from photosynthesis.

Overview

We discuss how we can read a planet's spectrum to assess its habitability and search for the signatures of a biosphere. After a decade rich in giant exoplanet detections, observation techniques have now reached the ability to find planets of less than $10 M_{\text{Earth}}$ (so-called ► [super-Earths](#)) that may potentially be habitable. Extrasolar planet searches have shown an extraordinary ability to combine research with astrophysics, chemistry, biology, and geophysics into a new and exciting interdisciplinary approach to understanding our place in the universe.

Introduction

The current status of exoplanet characterization shows a surprisingly diverse set of giant planets. For a subset of these, some properties have been measured or inferred using observations of the host star, a background star, or the combination of stellar and planetary photons (► [Radial-Velocity Planets](#), [Microlensing Planets](#), ► [Transiting Planets](#), and ► [Astrometry](#)). These observations have yielded measurements of planetary mass, orbital elements and (for transits) the planetary radius, and, during the last few years, physical and chemical characteristics of the upper atmosphere of some of the transiting planets.

The detection of an Earthlike planet is approaching rapidly thanks to radial velocity surveys (► [HARPS](#)), transit searches (Corot, Kepler), and space observatories dedicated to their characterization that are already in the

development phase (► [James Webb Space Telescope](#)), as well as future large ground-based telescopes and dedicated space-based missions. Space missions like CoRoT (CNES; Rouan et al. 1998) and Kepler (NASA; Borucki et al. 1997) provide statistics on the number, size, period, and orbital distance of planets, extending to terrestrial planets on the lower mass range end, while future space missions are designed to characterize their atmospheres.

Future space missions have the explicit purpose of detecting other Earthlike worlds, analyzing their characteristics, determining the composition of their atmospheres, investigating their capability to sustain life as we know it, and searching for signs of life. This can set our own planet, the only known habitat, in context with other rocky worlds and expand our statistics of 3 for extrasolar rocky planets that could potentially support life (► [Habitability of the Solar System](#)). They have the capacity to investigate the physical properties and composition of a broader diversity of planets, to understand the formation of planets, and to interpret potential biosignatures (see Fig. 1).

Basic Methodology

Characterize a Habitable Planet

A planet is a very faint, small object close to a very bright and large object, its parent star. In the visible part of the spectrum, we observe the starlight reflected off the planet, while in the infrared

Habitable Planet, Characterization, Fig. 1 Connection between spectra and characterization of rocky exoplanets

Habitable Planet, Characterization, Fig. 2 SAO model of our solar system (*left*) (assumed here to be black bodies with Earth spectrum shown). Spectra of different host stars (Segura et al. 2005) (*right*)

(IR), we detect the planet's own emitted flux. The Earth-Sun intensity ratio is about 10^{-7} in the thermal infrared ($\sim 10 \mu\text{m}$) and about 10^{-10} in the visible ($\sim 0.5 \mu\text{m}$) (see Fig. 2). The trade-off between contrast ratio and design is not discussed here, but leads to several different configurations for space-based mission concepts. The suggested interferometric systems operate in the mid IR ($6\text{--}20 \mu\text{m}$) and observe the thermal emission emanating from the planet. The coronagraph and occulter concepts detect the reflected light of a planet and operate in the visible and near infrared ($0.5\text{--}1 \mu\text{m}$). The viewing geometry results in different flux contributions of the overall detected signal from the planet's bright and dark side for the reflected light and the planet's hot and cold regions for the emitted flux. The contrast ratio of hot extrasolar giant planets (EGP) to their parent stars' flux is much smaller and can partially be observed with current telescopes. The contrast ratio of a rocky planet to a smaller parent star is much more favorable, making Earthlike planets around small stars very interesting targets for the immediate future.

Our search for signs of life is based on the assumption that extraterrestrial life shares fundamental characteristics with life on Earth, in that it requires liquid water as a solvent, has an energy source, and features a carbon-based chemistry (see,

e.g., Brack 1993; Des Marais et al. 2002). Life on the basis of a different chemistry is not considered here because the vast range of possible life-forms might produce signatures in their planet's atmosphere that are so far unknown. Therefore, we assume that extraterrestrial life is similar to life on Earth in its use of the same input and output gases and that it exists out of thermodynamic equilibrium (Lovelock 1975). ► **"Biomarkers"** are used here to mean detectable species, or a set of species, whose presence at significant abundance strongly suggests a biological origin (e.g., the simultaneous presence of $\text{CH}_4 + \text{O}_2$ or $\text{CH}_4 + \text{O}_3$ (Lovelock 1975)). Bioindicators are indicative of biological processes but can also be produced abiotically. It is their abundance and detection along with other atmospheric species and in a certain context (for instance, the properties of the star and the planet) that point toward a biological origin. The spectrum of the planet can contain signatures of atmospheric species, which creates its spectral fingerprint (► **Biomarkers Atmospheric**, ► **Evolution Over Geological Time** and ► **Biomarkers**, ► **Spectral**). Figure 3 shows observations and model fits to spectra of the Earth in three wavelength ranges (Kaltenegger et al. 2007). The data shown in Fig. 3 (left) is the visible Earthshine spectrum (Woolf et al. 2002), (right) is the near-infrared Earthshine spectrum (Turnbull et al. 2006), and

Habitable Planet, Characterization, Fig. 3 Observed reflectivity spectrum in the visible (Woolf et al. 2002) (top), near-infrared (Turnbull et al. 2006) (middle), and emission spectrum in the infrared (Christensen and Pearl

1997) (bottom panel) of the integrated Earth, as determined from Earthshine and space, respectively. The data is shown in black and the Smithsonian Astrophysical Observatory (SAO) model in red. The reflectivity scale is arbitrary

(bottom) is the thermal infrared spectrum of Earth as measured by a spectrometer en route to Mars (Christensen and Pearl 1997). The data are shown in black and the SAO model in red. In each case, the constituent gas spectra in a clear atmosphere are shown in the bottom panel, for reference.

Both spectral regions contain the signature of atmospheric gases that may indicate habitable conditions and, possibly, the presence of a

biosphere: CO₂, H₂O, O₃, CH₄, and N₂O in the thermal infrared and H₂O, O₃, O₂, CH₄, and CO₂ in the visible to near-infrared in reflected (Fig. 4 left). The Earth's spectra are shown in Fig. 4. The presence or absence of these spectral features (detected individually or collectively) will indicate similarities or differences with the atmospheres of terrestrial planets and their astrobiological potential (see Kaltenegger and

Habitable Planet, Characterization, Fig. 4 Synthetic reflection and emission spectra (*left*) and transmission spectra (*right*) of the Earth from UV to IR shown. The

intensity is given as a fraction of solar intensity (*left*) as well as the relative height in the atmosphere. The atmospheric features are indicated

Traub (2009) and Palle et al. (2009) for details on Earth's transmission spectrum).

Key Research Findings

Characterizing Planetary Environments

It is relatively straightforward to remotely ascertain that Earth is a habitable planet, replete with oceans, a greenhouse atmosphere, global geochemical cycles, and life – if one has data with arbitrarily high signal-to-noise ratio and spatial and spectral resolution. The interpretation of observations of other planets with limited signal-to-noise ratio and spectral resolution, as well as absolutely no spatial resolution as envisioned for the first-generation search instruments, will be far more challenging and implies that we need to gather information on the planetary environment to understand what we will see.

The following step-by-step approach can be taken to set the planetary atmosphere in context. After detection, we will focus on the main properties of the planetary system: its orbital elements as well as the presence of an atmosphere, using the light curve of the planet, or/and a crude estimate of the planetary nature from very low-resolution information (three or four wavelength channels).

Then a higher-resolution spectrum will be used to identify the compounds of the planetary atmosphere and to constrain the temperature and radius of the observed exoplanet. In that context, we can then test if we have an abiotic explanation of all compounds seen in the atmosphere of such a planet. If we do not, we can work with the exciting biotic hypothesis. O_2 , O_3 , and CH_4 are good biomarker candidates that can be detected by a low-resolution (resolution <50) spectrograph. Note that if the presence of sets of biogenic gases such as ($O_2/O_3 + CH_4$) may imply the presence of a massive and active biosphere, their absence does not imply the absence of life. Life existed on Earth before the interplay between oxygenic photosynthesis and carbon cycling produced an oxygen-rich atmosphere.

Temperature and Radius of a Planet

Knowing the temperature and planetary radius is crucial for the general understanding of the physical and chemical processes occurring on the planet (tectonics, hydrogen loss to space). In theory, spectroscopy can provide some detailed information on the thermal profile of a planetary atmosphere (► [Atmosphere](#), Structure). This, however, requires a spectral resolution and a sensitivity that are well beyond the

performance of a first-generation spacecraft. Here we concentrate on the initially available observations.

One can calculate the stellar energy of the star F_{star} that is received at the planet's measured orbital distance. The surface temperature of the planet at this distance depends on its [albedo](#) and on the greenhouse warming by atmospheric compounds. However, with a low-resolution spectrum of the thermal emission, the mean effective temperature and the radius of the planet can be obtained. The ability to associate a surface temperature to the spectrum relies on the existence and identification of spectral windows (regions of transparency) which allow probing the surface or certain atmospheric levels. Such identification is not trivial. For an Earthlike planet, there are some atmospheric windows that can be used in most of cases, especially between 8 and 11 μm as seen in Fig. 4. This window would, however, become opaque at high H_2O partial pressure (e.g., in the inner part of the [habitable zone](#) (HZ) where a lot of water is vaporized) and at high CO_2 pressure (e.g., a very young Earth or the outer part of the HZ). The accuracy of the radius and temperature determination will depend on the sensitivity and resolution of the spectrum, the precision of the Sun-star distance, the cloud coverage, and also the distribution of brightness temperatures over the planetary surface. For transiting planets, the

accuracy of the radius of the planet depends on how well the host star is characterized.

The measured IR flux can directly be converted into a brightness temperature that will provide information on the temperature of the atmospheric layers responsible for the emission. If the mass of a planet can be measured (by radial velocity and/or astrometric observations), an estimate of the radius of the rocky core can be made by assuming a bulk composition of the planet which can then be used to convert IR fluxes into temperatures. Important phase-related variations in the planet's flux are due to a high day/night temperature contrast and imply a low [greenhouse effect](#) and the absence of a stable liquid ocean. Therefore, habitable planets can be distinguished from airless or Mars-like planets by the amplitude of the observed variations of T_b (see Fig. 5).

The orbital flux variation in the IR can distinguish (in the detection phase) planets with and without an atmosphere (see also Selsis 2002; Gaidos and Williams 2004). Strong variation of the thermal flux with the phase reveals a strong difference in temperature between the day and night hemisphere of the planet, a consequence of the absence of a dense atmosphere which would transport heat between the hemispheres. In such a case, estimating the radius from the thermal emission is made difficult because most of the received flux comes from the small and hot substellar area.

Habitable Planet, Characterization, Fig. 5 Orbital [light curve](#) for [blackbody](#) planets in a circular orbit with null obliquities, with and without an atmosphere in

the visible (*left*) and thermal infrared (*right*) (After Selsis 2002). Flux normalized to the average over a complete period

The ability to retrieve the radius would depend on the assumptions that can be made on the orbit geometry and the rotation rate of the planet (► [Habitable Zone](#), ► [Effect of Tidal Locking](#)). In most cases, degenerate solutions will exist. When the mean brightness temperature is stable along the orbit, the estimated radius is more reliable. The radius can be measured at different points of the orbit and thus for different values of brightness temperature T_b , which should allow estimating the error made.

Note also that a Venus-like exoplanet would exhibit nearly no measurable phase-related variation of its thermal emission, due to the fast rotation of its atmosphere and its strong greenhouse effect, and thus can only be distinguished through spectroscopy from habitable planets. The mean value of T_b estimated over an orbit can be used to estimate the ► [albedo](#) of the planet, A , through the balance between the incoming stellar radiation and the outgoing IR emission.

The thermal light curve (i.e., the integrated infrared emission measured at different positions on the orbit) exhibits smaller variations due to the phase (whether the observer sees mainly the day-side or the nightside) and to the season for a planet with an atmosphere, than does the corresponding visible light curve (see Fig. 5). In the visible ranges, the reflected flux allows us to measure

the product $A \times R^2$, where R is the planetary radius (a small but reflecting planet appears as bright as a big but dark planet). The first generation of optical instruments will be very far from the angular resolution required to directly measure an exoplanet radius.

Potential Biomarkers

Spectral ► [biomarkers](#) are discussed in a separate entry in this encyclopedia. We simply add here Fig. 6 on the terrestrial oxygen cycle. Note that possible abiotic sources of biomarkers must be carefully evaluated.

Cryptic Worlds, Surface Features and Cloud Features

► [Clouds](#) reduce the relative depths, full widths, and equivalent widths of spectral features, weakening the spectral lines in the whole described as wavelength range (Kaltenegger et al. 2007). Earth has an average of 60% cloud coverage, which prevents easy identification of any surface features without knowing the cloud distribution. If one records the planet’s signal with a very high time resolution (a fraction of the rotation period of the planet) and individually high signal-to-noise ratio (SNR), one could determine the overall contribution of clouds to the signal (Cowan et al. 2009; Palle et al. 2008). During each of these

Habitable Planet, Characterization, Fig. 6 Oxygen cycle on Earth (Kaltenegger and Selsis 2010); Gt is gigatons

individual measurements, one has to collect enough photons for a high individual SNR per measurement to be able to correlate the measurements to the surface features, which precludes this method for first-generation missions that will observe a minimum of several hours to achieve an SNR of 5–10. For Earth (Cowan et al. 2009; Palle et al. 2008), these measurements show a correlation to Earth's surface features, because the individual measurements are time resolved as well as have an individual high SNR, making it a very interesting concept for future generations of missions.

Assuming one had a planet with a cloud-free atmosphere or could distinguish the signal from the overall cloud distribution from that due to the surface reflectivity, one could discover continents and seas on an exoplanet by observing the daily variation of the surface albedo in the visible (Ford et al. 2001; Palle et al. 2008). On a cloud-free Earth, the diurnal flux variation at visible wavelengths caused by different surface features rotating in and out of view could be high, assuming hemispheric inhomogeneity. When the planet is only partially illuminated, a more concentrated signal from surface features could be detected as they rotate in and out of view on a cloudless planet (William and Gaidos 2008).

Our knowledge of the reflectivity of different surface components on Earth – like desert, ocean, and ice – helps in assigning the vegetation red edge (VRE) of the Earthshine spectrum to terrestrial vegetation. On Earth around 440 million years ago (Pavlov et al. 2003; Schopf 1993), an extensive land plant cover developed, generating the red chlorophyll edge in the reflection spectrum between 700 and 750 nm. While they efficiently absorb visible light, photosynthetic plants have developed strong infrared reflection (possibly as a defense against overheating and chlorophyll degradation) resulting in a steep change in reflectivity around 700 nm, called the red edge. The primary molecules that absorb the energy and convert it to drive photosynthesis (H_2O and CO_2 into sugars and O_2) are chlorophyll A (0.450 μm) and B (0.680 μm). The exact wavelength and strength of the spectroscopic “vegetation red

edge” (VRE) depend on the plant species and environment. Averaged over a spatially unresolved hemisphere of Earth, the additional reflectivity of this spectral feature is typically only a few percent (see also (Montanes-Rodriguez et al. 2005; Tinetti et al. 2006; Kaltenegger and Traub 2009). Several groups (Arnold et al. 2002; Christensen and Pearl 1997; Montanes-Rodriguez et al. 2007; Woolf et al. 2002; Turnbull et al. 2006) have measured the integrated Earth spectrum via the technique of Earthshine, using sunlight reflected from the non-illuminated, or “dark,” side of the Moon. Earthshine measurements have shown that detection of Earth's VRE is feasible if the resolution is high and the cloud coverage is known. On planets around other stars, different biota could develop and produce different reflective features (Kiang et al. 2007).

On Earth, photosynthetic organisms are responsible for the production of nearly all of the oxygen in the atmosphere. However, in many regions of the Earth and particularly where surface conditions are extreme, for example, in hot and cold deserts, photosynthetic organisms can be driven into and under substrates where light is still sufficient for photosynthesis. These communities exhibit no detectable surface spectral signature. The same is true of the assemblages of photosynthetic organisms at more than a few meters depth in water bodies. These communities are widespread and dominate local photosynthetic productivity. There could be such very interesting Earth-analog worlds that could have habitats but not exhibit biological surface feature in the disk-averaged spectrum (Cockell et al. 2009).

Earth's hemispherical integrated vegetation red edge signature is very weak, but planets with different rotation rates, obliquities, land-ocean fraction, and continental arrangement may have lower cloud cover and higher vegetated fraction. Knowing that other pigments exist on Earth and that some minerals can exhibit a similar spectral shape around 750 nm (Seager et al. 2005), the detection of the red edge of chlorophyll on exoplanets, despite its extreme interest, will not be unambiguous.

Summary

Any information we collect on habitability is only important in a context that allows us to interpret what we find. To search for signs of life, we need to understand how the observed atmosphere physically and chemically works. Knowledge of the temperature and the planetary radius is crucial for the general understanding of the physical and chemical processes occurring on the planet. These parameters, as well as an indication of habitability, can be determined with low-resolution spectroscopy and low photon flux, as assumed for first-generation space missions. The combination of spectral information in the visible (starlight reflected off the planet) as well as in the mid IR (planet's thermal emission) allows a confirmation of detection of atmospheric species and a more detailed characterization of individual planets and the opportunity to explore a wide domain of planet diversity. Being able to measure the outgoing shortwave and longwave radiation as well as their variations along the orbit, to determine the albedo and identify greenhouse gases, would in combination allow us to explore the climate system at work on the observed worlds, as well as probe planets similar to our own for habitable conditions.

Future Directions

The results of a first-generation mission will most likely include an amazing scope of diverse planets that will set planet formation and evolution, as well as our own planet, in an overall context.

Definition

The circumstellar habitable zone (HZ) is the circular region around one or multiple stars where standing bodies of liquid water could exist on a rocky planet’s surface similar to Earth in composition and mass with an atmosphere (e.g., Kasting et al. 1993; Haghighipour and Kaltenegger 2012; Kaltenegger and Haghighipour 2013; Kopparapu et al. 2013) that facilitates the detection of possible atmospheric biosignatures in the atmosphere of such planets (see, e.g., Kaltenegger 2017; Catling et al. 2018; Fujii et al. 2018).

The width and distance of this annulus, using this definition, depend mainly on the stellar luminosity and spectral energy distribution, and change through stellar evolution (Underwood et al. 2003; Lopez et al. 2005; Danchi and Lopez 2013; Ramirez and Kaltenegger 2014, 2016).

A planet in the habitable zone is not necessarily habitable. Multiple mechanisms exist by which a planet cannot attain or can lose habitability, for example, low mass and resulting atmospheric losses or changes in initial composition (e.g., no water). The HZ is a tool that guides missions and surveys in prioritizing planets for follow-up observations.

History

The habitable zone (HZ) concept was proposed for the first time by Huang (1959, 1960) and has been calculated by several authors after that (see, e.g., Rasool and DeBergh 1970; Hart 1979; Kasting et al. 1993; Kopparapu et al. 2012; Underwood et al. 2003; Lopez et al. 2005; Ramirez and Kaltenegger 2016, 2018). The most used limits have been those calculated by Kasting et al. (1993) and later recalculated by Kopparapu et al. (2012), and it is usually called the classic habitable zone. These limits were calculated with 1D cloudless atmospheric models.

New limits of the habitable zone have been calculated by including properties of the planet and the star, as well as 3D models. For example, the internal limit of the habitable zone is closer to the star – compared to the one calculated by

Kopparapu et al. (2012) – for rocky planets with low water inventory in the planetary surface (Abe et al. 2011). Clouds widen the habitable zone moving the inner limit (water clouds) and the outer limit farther from the star (CO₂ clouds) (e.g., Selsis et al. 2007). For low mass main sequence stars (M dwarfs), the habitable zone is so close to the host star that planets enter spin-orbit resonances changing the limits of the habitable zone (Wordsworth et al. 2011; Turbet et al. 2016). Other variations for the calculation of the habitable zone include H₂ atmospheres (Pierrehumbert and Gaidos 2011; Ramirez and Kaltenegger 2017), methane (Ramirez and Kaltenegger 2018), hazes (Arney et al. 2017), and the ice albedo feedback (Joshi and Haberle 2012; Shields et al. 2013). Three-dimensional studies (e.g., Leconte et al. 2013) suggest that the inner HZ edge could be closer to the star (than predicted by some 1D models) due to a Hadley cell response such that IR cooling to space is shifted to lower altitudes where it is more efficient.

Given that stellar luminosity evolves during the star's lifetime, the concept of a continuously habitable zone (CHZ) has been introduced to mean the zone that remains habitable around a star during a given period of time (Hart 1979).

Overview

Future remote sensing characterization of planetary environments can be used to test our understanding of the factors that contribute to planetary habitability. The HZ is usually defined for surface conditions only. Chemoautotrophic life, whose metabolism does not depend on the stellar light, can still exist outside the HZ, thriving in the interior of the planet where liquid water is available. Such metabolisms rely on very limited sources of energy (compared to stellar light) and electron donors (compared to H₂O on Earth). They mainly catalyze reactions that would occur at a slower rate in purely abiotic conditions, and they are thus not expected to modify a whole planetary environment in a way detectable remotely.

Basic Methodology

The limits of classic habitable zone were calculated using a 1D atmospheric model for planets with H₂O-CO₂-N₂ atmospheres (Kasting et al. 1993; Kopparapu et al. 2013). The procedure relied on the inverse climate modeling calculating the flux needed to achieve a given atmospheric setup, instead of obtaining a temperature profile for a given solar flux. The solar or stellar flux is expressed as the effective solar/stellar flux (S_{eff}), that is the solar flux divided by the solar constant ($S_{\odot} = 1360 \text{ W m}^{-2}$, Kopparapu et al. 2013). The solar constant is the integrated solar flux at the top of the atmosphere for present Earth.

For the outer boundary, the model calculated the flux and the CO₂ surface pressure needed to keep the surface temperature at 273 K. As the planet receives less stellar flux, the atmospheric CO₂ is increased in the model until it fails to keep this temperature, this is known as the maximum greenhouse limit. The outer edge limit can change significantly if other gases are added to the model like hydrogen and methane (Pierrehumbert and Gaidos 2011; Ramirez and Kaltenegger 2017, 2018).

The inner limit is determined by the moist-greenhouse effect where the atmosphere losses the cold trap that keeps the water in the troposphere; once H₂O reaches the stratosphere, it is photolyzed and hydrogen escapes to space (Kasting et al. 1993; Kopparapu et al. 2013). There is a second boundary for the internal HZ, called the runaway greenhouse limit, when the oceans are totally evaporated. To calculate both limits, the model determined the solar flux needed to achieve temperatures from 220 K to 2200 K. The inner edge is relatively robust to additions of secondary greenhouse gases, because trace gas absorption is outstripped by water vapor absorption in these extremely dense (>200 bar) water steam atmospheres.

A revision of the calculations by Kasting et al. (1993) reported values of $S_{\text{eff}} = 1.04$ for the inner edge of the Sun HZ (runaway greenhouse limit) and 0.35 for the outer edge of the Sun HZ (assuming a maximum greenhouse effect in the planet's atmosphere; see Kopparapu et al. 2012,

2013). The distance around a star with luminosity L where a planet receives an effective flux S_{eff} is:

$$d = \left(\frac{L/L_{\odot}}{S_{\text{eff}}} \right) \text{au}$$

Thus, the inner edge of the solar HZ using 1D models without cloud feedback is at 0.99 au (moist greenhouse) and the outer edge at 1.7 au. Another set of boundaries for the HZ are called “empirical limits” because they use the cases of Venus and Mars. The inner HZ empirical limit is defined by the S_{eff} received by Venus when it may have lost most of its water by runaway greenhouse (about 1 Gyr ago), that is $S_{\text{eff}} = 1.77$ (0.75 au for the present solar luminosity). The outer edge is defined by the effective solar flux that Mars received at the time that it may have had stable water on its surface (about 3.8 Gyr ago), which corresponds to $S_{\text{eff}} = 0.32$ (1.77 au for the present solar luminosity). Note that the inner edge of the empirical habitable zone is highly uncertain because of the unknown evolution of Venus.

Kopparapu et al. (2013) used the same methodology for the Sun and for F, G, K, and M main sequence stars, obtaining a general relationship for calculating the limits of the habitable zone valid for main sequence stars with effective temperatures (T_{eff}) from 2600 K to 7200 K. Ramirez and Kaltenegger (2016) extended those limits to main sequence stars with 10,000 K.

For calculations of the HZ limits, it is assumed that planets have similar mass to Earth, rocky compositions and the surface temperature is controlled by a global carbonate-silicate cycle that stabilizes the CO_2 level, like on Earth (Walke 1977). This implies that the planet is geologically active and continuously outgasses CO_2 and that carbonates form in the presence of surface liquid water, which may require continental weathering. Without this stabilization, the Earth would not be habitable over geological times. This in turn affects the composition of the atmosphere at the outer edge of the habitable zone. As the amount of CO_2 increases, the greenhouse effect increases, warming the surface and releasing more CO_2 from carbonates and from that dissolved in

oceans. The feedback only works up to the temperature where the increase in the albedo due to increasing in CO_2 concentration (producing more Rayleigh scattering and cloud formation; see, e.g., Forget and Pierrehumbert 1997) is stronger than the greenhouse effect of CO_2 . Because of the relation between the albedo of the planet and the effective temperature of the star, the limits of the habitable zone cannot be simply scaled to the stellar luminosity.

Key Research Findings

The limits of the circumstellar habitable zone (HZ) around a main sequence star are given in Table 1. However, the limits of the HZ are known qualitatively, more than quantitatively. This uncertainty is mainly due to the complex role of ► clouds and three-dimensional climatic effects not yet included in the modeling. Thus, planets slightly outside the computed HZ could still be habitable, while planets at habitable orbital distance may not be habitable because of their size, chemical composition, or other characteristics that could prevent habitability.

Applications

The concepts of the HZ help to define an astronomical search zone for habitable planets with remotely detectable species in their atmosphere that indicate habitable conditions, such as surface liquid water (e.g., Segura and Kaltenegger 2010; Kaltenegger 2017).

Future Directions

The habitable zone concept is still evolving as more is learnt about planetary formation and evolution and as we continue to improve the radiative transfer, ► clouds, and three-dimensional atmospheric models that allow more accurate calculations of a planet’s temperature profile. The recollection of more data from detected exoplanets and their host stars allows the inclusion

Habitable Zone, Table 1 Properties and habitable zone limits of the main sequence stars of spectral type F-M considered for the search of Earth analogs, assuming no

other limits than runaway and maximum greenhouse for a rocky planet with CO₂ atmosphere. Note that this model does not take increasing cloud fractions into account

Habitable Zone Around Binary Star Systems

Nader Haghighipour

Institute for Astronomy, University of Hawaii-Manoa, Honolulu, HI, USA

Keywords

Exoplanets · Habitability · Life

Definition

In a binary star system, a planet may in principle exist in an orbit around either of the stars or in an orbit that surrounds both stars of the binary. In the latter case, we refer to the planet as a ► **circumbinary planet**. The corresponding habitable zone (HZ) may be assumed to be an annulus around the binary where an Earth-like planet (with

similar atmospheric composition to that of Earth) with a sufficient amount of water can permanently maintain liquid water on its solid surface.

Basic Methodology

To calculate the boundaries of the habitable zone (HZ) around a binary star system (circumbinary orbits), it is assumed that the HZ is an annulus around the binary where an Earth-like planet (with similar atmospheric composition as that of Earth) and sufficient amount of water can permanently maintain liquid water on its solid surface. The locations of the boundaries of the HZ, and therefore the capability of the planet in maintaining conditions for habitability, depend on the total flux received at the top of its atmosphere. Since the atmosphere converts stellar insolation to temperature structure and surface temperature of a planet, its interaction with the stellar radiation plays an important role in considering whether a planet can maintain liquid water on its surface and allow for detectable habitable conditions. This interaction strongly depends on the stellar spectral energy distribution (SED), implying that stars with different energy distributions will contribute differently to the absolute incident flux at the top of the planet's atmosphere. To determine the contribution of a star taking into account its SED, it is necessary to define a *spectral weight factor* $W_i(f, T_i)$, where $i = (\text{Pr}, \text{Sec})$ denoting the primary and secondary stars, respectively, T_i is the star's effective temperature and f represents the atmosphere's cloud fraction. The contribution of each star of the binary to the total flux at the top of the planet's atmosphere can be therefore written as

$$W_i(f, T_i)F_i(f, T_i).$$

Here $F_i = L_i/r_{\text{Pl}-i}^2$ denotes the stellar flux and L_i is the luminosity of each star of the binary. The total flux received by the planet is therefore given by

$$W_{\text{Pr}}(f, T_{\text{Pr}}) \frac{L_{\text{Pr}}(T_{\text{Pr}})}{r_{\text{Pl}-\text{Pr}}^2} + W_{\text{Sec}}(f, T_{\text{Sec}}) \frac{L_{\text{Sec}}(T_{\text{Sec}})}{r_{\text{Pl}-\text{Sec}}^2},$$

where $r_{\text{Pl}-\text{Pr}}$ and $r_{\text{Pl}-\text{Sec}}$ are the distances between the planet and the primary and secondary stars, respectively. Defining HZ as a region where the total flux received by an Earth-like planet at the top of its atmosphere is equal to that of Earth received from the Sun, the boundaries of circumbinary HZ can be calculated from

$$\begin{aligned} W_{\text{Pr}}(f, T_{\text{Pr}}) \frac{L_{\text{Pr}}(T_{\text{Pr}})}{l_{x-\text{Bin}}^2} + W_{\text{Sec}}(f, T_{\text{Sec}}) \frac{L_{\text{Sec}}(T_{\text{Sec}})}{r_{\text{Pl}-\text{Sec}}^2} \\ = \frac{L_{\text{Sun}}}{l_{x-\text{Sun}}^2}. \end{aligned}$$

where x -inner, outer boundary of the HZ.

In deriving this equation, it is assumed that the primary star is at the center of the coordinates system (see the entry ► [Circumbinary Planet](#)) and the boundaries of the HZ of the binary ($l_{x-\text{Bin}}$) are measured with respect to this star.

The functional form of the spectral weight factor $W_i(f, T_i)$ varies according to the models of the Sun's HZ. Haghighipour and Kaltenegger (2013) have developed a detailed methodology for calculating this quantity. Mueller and Haghighipour (2014) have utilized that methodology and created a website with a user interface where one can input the physical and orbital parameters of the binary, and the website generates a snapshot of the circumbinary HZ corresponding to those orbital elements. This website can be found at <http://astro.twam.info/hz/>.

As implied by the above equation for calculating the HZ, the inner and outer boundaries of the HZ vary as the stars of the binary rotate around their center of mass. A gallery of the HZs of all currently known circumbinary planets with movies of their time variations can be found at <http://astro.twam.info/hz-ptype/>.

It is important to note that in reality, the habitability of an Earth-like planet in a circumbinary HZ is independent of the fluctuations of the boundaries of the HZ. In this case, the determining factor is the averaged flux received by the planet in one orbit around the binary. During this time, the buffering effect of clouds should compensate for the effects of the temporary displacements of the HZ and allow the planet to maintain a surface

Exoplanets · Habitability · Life

Definition

In a binary star system, a planet may in principle exist either in an orbit around a star or in an orbit that surrounds both stars in the system; in the former case, we refer to it as a ► **circumprimary planet**. To calculate the boundaries of the habitable zone (HZ) around a star of a binary star system (circumprimary orbits), it is assumed that the HZ is an annulus around the star where an Earth-like planet (with similar atmospheric composition to that of Earth) and a sufficient amount of water can permanently maintain liquid water on its solid surface.

Basic Methodology

The locations of the boundaries of the HZ, and therefore the capability of the planet in maintaining conditions for habitability, depend on the total flux received at the top of its atmosphere. Since the atmosphere converts stellar insolation to temperature structure and surface temperature of a planet, its interaction with the stellar radiation plays an important role in considering whether a planet can maintain liquid water on its surface and allow for detectable habitable conditions. This interaction strongly depends on the stellar spectral energy distribution (SED), implying that stars with different energy distributions will contribute differently to the absolute incident flux at the top of the planet's atmosphere. To determine the contribution of a star taking into account its SED, it is necessary to define a *spectral weight factor* $W_i(f, T_i)$, where $i = (\text{Pr}, \text{Sec})$ denoting the primary and secondary stars, respectively, T_i is the star's effective temperature, and f represents the atmosphere's cloud fraction. The contribution of each star of the binary to the total flux at the top of the planet's atmosphere can be therefore written as $W_i(f, T_i)$. Here

$$F_i = L_i / r_{\text{Pl}-i}^2$$

denotes the stellar flux and L_i is the luminosity of each star of the binary. The total flux received by the planet is therefore given by

$$W_{\text{Pr}}(f, T_{\text{Pr}}) \frac{L_{\text{Pr}}(T_{\text{Pr}})}{r_{\text{Pl-Pr}}^2} + W_{\text{Sec}}(f, T_{\text{Sec}}) \frac{L_{\text{Sec}}(T_{\text{Sec}})}{r_{\text{Pl-Sec}}^2},$$

where $r_{\text{Pl-Pr}}$ and $r_{\text{Pl-Sec}}$ are the distances between the planet and the primary and secondary stars, respectively. Defining HZ as a region where the total flux received by an Earth-like planet at the top of its atmosphere is equal to that of Earth received from the Sun, the boundaries of circumprimary HZ can be calculated from

$$\begin{aligned} W_{\text{Pr}}(f, T_{\text{Pr}}) \frac{L_{\text{Pr}}(T_{\text{Pr}})}{l_{\text{x-Bin}}^2} + W_{\text{Sec}}(f, T_{\text{Sec}}) \frac{L_{\text{Sec}}(T_{\text{Sec}})}{r_{\text{Pl-Sec}}^2} \\ = \frac{L_{\text{Sun}}}{l_{\text{x-Sun}}^2}. \end{aligned}$$

In deriving this equation, it is assumed that the primary star is at the center of the coordinates system (see the entry ► **Circumprimary Planet**) and the boundaries of the HZ of the binary ($l_{\text{x-Bin}}$) are measured with respect to this star.

The functional form of the spectral weight factor $W_i(f, T_i)$ varies according to the models of the Sun's HZ. Kaltenegger and Haghighipour (2013) have developed a detailed methodology for calculating this quantity. Mueller and Haghighipour (2014) have utilized that methodology and created a website with a user interface where one can input the physical and orbital parameters of the binary, and the website generates a snapshot of the circumprimary HZ corresponding to those orbital elements. This website can be found at <http://astro.twam.info/hz/>

As implied by the above equation for calculating the HZ, the inner and outer boundaries of the HZ vary as the stars of the binary rotate around their center of mass. It is important to note that in reality the habitability of an Earth-like planet in a circumprimary HZ is independent of the fluctuations of the boundaries of the HZ. In this case, the determining factor is the averaged flux received by the planet in one orbit of the binary. During this time, the buffering effect of clouds should compensate for the effects of the temporary

habitable conditions. This interaction strongly depends on the stellar spectral energy distribution (SED), implying that stars with different energy distributions will contribute differently to the

absolute incident flux at the top of the planet's atmosphere. To determine the contribution of a star taking into account its SED, it is necessary to define a *spectral weight factor* $W_i(f, T_i)$,

Habitable Zone in Multi-star Systems, Fig. 3

HZ of a system of three 0.25 solar mass M stars in a figure-eight orbit. From the *top to bottom*, the figures show the evolution of the HZ of the system for one complete revolution around its center of mass. The *dashed circles* show the boundaries of the regions of planetary stability around each star (~ 0.101 AU). As shown here, Earth-like planets can have stable orbits in a small region in the empirical HZ around each star. An animation of the HZ of this system can be found at <http://astro.twam.info/hz-multi> (Mueller and Haghighipour 2014)

where i denotes the i th star, T_i is the star's effective temperature, and f represents the atmosphere's cloud fraction. The contribution of each star of the system to the total flux at the top of the planet's atmosphere can be therefore written as

$$W_i(f, T_i)F_i(f, T_i).$$

Here $F_i = L_i/d_i^2$ denotes the stellar flux where L_i is the luminosity of the i th star of the system and d_i is the distance from star i to the planet. The total flux received by the planet is therefore given by

$$F_{\text{total}} = \sum_{i=1}^N W_i(T_i) \frac{L_i}{d_i^2}.$$

Defining HZ as a region where the total flux received by an Earth-like planet at the top of its atmosphere is equal to that of Earth received from the Sun, the boundaries of a multi-star HZ can be calculated from

$$\sum_{i=1}^N W_i(T_i) \frac{L_i}{d_i^2} = \frac{L_{\text{Sun}}}{l_{x-\text{Sun}}^2}.$$

where $x = (\text{In}, \text{Out})$, and $l_{x-\text{Sun}}$ denotes the boundaries of the Sun's HZ. Any point in the HZ of the system will satisfy the condition

$$\frac{L_{\text{Sun}}}{l_{\text{In-Sun}}^2} \leq \sum_{i=1}^N W_i(T_i) \frac{L_i}{d_i^2} \leq \frac{L_{\text{Sun}}}{l_{\text{Out-Sun}}^2},$$

In deriving this equation, it is assumed that the center of mass of the system is at the center of the coordinate system (Mueller and Haghighipour 2014). Figure 1 shows snapshots of the HZ of the triple star system KIC 4150611 from *Kepler* Input Catalog.

The functional form of the spectral weight factor $W_i(f, T_i)$ varies according to the models of the Sun's HZ. Haghighipour and Kaltenegger (2013) have developed a detailed methodology for calculating this quantity. Mueller and Haghighipour (2014) have utilized that methodology and created a website with a user interface where one can input the physical and orbital parameters of the binary, and the website generates a snapshot of the circumbinary HZ corresponding to those orbital elements. This

website can be found at <http://astro.twam.info/hz/>. Figure 2 shows a screenshot of this website.

As implied by the above equation for calculating the HZ, the inner and outer boundaries of the HZ vary as the stars rotate around their center of mass. However, it is important to note that in reality the habitability of an Earth-like planet is independent of the fluctuations of the boundaries of the HZ. In this case, the determining factor is the averaged flux received by the planet in one orbit. During this time, the buffering effect of clouds should compensate for the effects of the temporary displacements of the HZ and allow the planet to maintain a surface temperature conducive to liquid water. Figure 3 shows the HZ of an interesting triple star system in the famous figure-eight orbit (Mueller and Haghighipour 2014).

Habitable Zone, Effect of Tidal Locking

Lisa Kaltenegger

Cornell University, Ithaca, NY, USA

Keywords

Biomarkers · Habitability · Habitable zone · M stars · Resonance · Tidal locking

Definition

Tidal locking is a state of dynamical equilibrium between a planet's spin and orbital angular momentum. Tidally locked planets on circular orbits may become synchronous rotators, presenting the same solid-body hemisphere to the star.

Overview

Tidally locked planets on circular orbits may become synchronous rotators, presenting the same solid-body hemisphere to the star. If the planet's orbit is eccentric, either due to a primordial condition or maintained by interactions with other planets, then the rotation period will be less than the orbital period and the planet will not synchronously rotate. Planets interior to the tidal lock radius may also become trapped in spin-orbit resonances, where they complete an integer ratio of rotations on their axis to orbits around their star. For example, Mercury is within the Sun's tidal lock radius in a 3:2 spin-orbit resonance, completing three rotations on its axis every two revolutions (orbits) around the Sun. For an M dwarf (less massive and cooler than the Sun), the ► [Habitable Zone](#) is so close to the star that the planets are likely to become tidally locked within a relatively short time after they form (Dole 1964; Kasting et al. 1993), but several resonances are possible. Only a planet in a 1:1 resonance receives starlight on only one hemisphere. Detailed models have shown that this does not prevent habitability for planets with even modestly dense atmospheres (Haberle et al. 1996; Joshi et al. 1997; Joshi 2003). Even a tidally locked 'Earth' could remain habitable, provided that atmospheric cycles transport sufficient heat from the dayside to the nightside.

Habitat

Felipe Gomez

Centro de Astrobiología (CSIC/INTA), Instituto Nacional de Técnica Aeroespacial, Torrejón de Ardoz, Madrid, Spain

Synonyms

[Ecosystem](#)

Definition

Habitat is the location in an ► [environment](#) which can be colonized by a biological population. In nature, organisms live in association with other organisms in assemblages called populations. The components and number of individuals in a habitat are governed by the resources and conditions that exist in the habitat. Habitats differ markedly in their characteristics, and a habitat that is favorable for the development of one organism may actually be harmful for another organism. From an astrobiological point of view, habitat is deeply related to the habitability concept which refers to the conditions that can support life in an adverse surrounding.

Definition

The earliest eon of geological time, extending from accretion of the Earth (4.567 Ga) to the formation of the earliest known rocks. The oldest rocks currently identified are components of the Acasta gneisses in the Northwest Territories of Canada (4.03 Ga). This date was determined as marking the lower limit of the Hadean by the Precambrian Subcommission on Stratigraphy in 2012. The ages have been rounded to ~4600 Ma and 4000 Ma for the commencement and termination of the Hadean, respectively, as shown on the International Chronostratigraphic Chart.

Overview

The term Hadean was coined in 1972 by Preston Cloud to designate that period of geological time

prior to formation of the earliest known rocks. It was derived from Greek mythology where “ Ἅδης = Hades” first referred to the God of the Underworld and later to the Underworld itself. In geological usage, it is commonly equated with “Hell,” based on the perception that the Earth was extremely hot and turbulent at that time. “Hadean” was an informal term for many years, partly because of the diversity of views as to its precise duration and to more recent work that questioned whether much of this time period on Earth was really “hell like”. Its starting point was variously taken as the formation of the planetary nebula, the onset of accretion, or the time from when the Earth was largely solid. Its termination was placed at 3.8/3.9 Ga by some workers, the age of the most ancient rocks in Greenland. However, more recent usage placed it at 4.0 Ga, based on the age of the world’s oldest gneisses at Acasta, Canada (Bowring and Housh 1995; Bowring and Williams 1999). Identification of zircon crystals up to 4.4 Ga, particularly from the Jack Hills in Western Australia, has led to the view that the Earth had cooled down sufficiently by ~4.3 Ga to support oceans and stable continents (Wilde et al. 2001; Valley et al. 2002), based on the study of oxygen and lithium isotopes in pristine zircon domains. This raised the question as to whether the term “Hadean” should be restricted to the period of time before the formation of oceans and continents, when the surface of the Earth was too hot and unstable to allow liquid water to form and rocks to survive. Furthermore, some workers who did not support the use of “Hadean” preferred to extend the Eoarchean back to incorporate this period of geological time. Further complicating the issue was that another term had been introduced into the literature for essentially the same period of time: “Priscoan”, coined by Brian Harland in 1989 (Harland et al. 1990), although few published articles have used this name. However, in 2012, following extensive discussion by the Precambrian Subcommission, “Hadean” was officially ratified by the International Commission on Stratigraphy. It was accepted that it commenced with the onset of formation of the Earth/Solar System and that it terminated with the oldest known rocks preserved on Earth.

In the past decade, no older rocks have been identified and there has been no requirement to consider modifying the Hadean boundaries. However, the number of localities where Hadean zircon has been identified has increased and they have now been found in Africa, Asia, Australasia, North America, and South America. Although Eoarchean rocks are present in Antarctica and Europe, unequivocal Hadean zircon ages have yet to be determined.

Planetary-scale geological processes took place during the Hadean eon, from the accretion of the Earth to its differentiation into a metallic core, a silicate mantle, and a primordial crust. However, the effect of any Late Heavy Bombardment (Cohen et al. 2000) on Earth has not been established and there is no record of it in either the Hadean zircon or the Eoarchean rocks that overlap with the proposed timing of such an event. Continental crust developed earlier than previously thought, based on geological information retained by the Jack Hills zircons. Several authors speculate that plate tectonics could also have started during the Hadean, yet geological evidence for this is still controversial. A detailed account of these processes is reported in *Earth, Formation and Early Evolution*.

Hadean Mantle

Maud Boyet
Université Blaise Pascal, Clermont-Ferrand,
France

Keywords

Isotope systematics · Early Earth · Magma ocean · Mantle dynamics · Moon-forming impact

Definition

The structure and the composition of the Hadean mantle are difficult to constrain due to the sparse geological record from this period. Isotope systematics show that the silicate Earth experienced global differentiation events during its infancy.

Strong chemical fractionations and an extensive loss of volatile elements are related to several magma ocean stages, the last one following the giant impact forming the Moon. Although during the Hadean, the mantle must have been hotter and the convection more vigorous, early chemical heterogeneities have not been erased until the Archean, questioning the regime of the Hadean mantle convection.

Overview

The Hadean eon corresponds to the earliest period of Earth's history starting from the beginning of solar system accretion (4.567 Ga, Connelly et al. 2012) to the oldest preserved rocks dated by U-Pb systematics (4.03 Ga, Acasta Gneiss, Bowring and Williams 1999). Geological records from this period that have been preserved over Earth's history are scarce and mostly consist of detrital zircons (Wilde et al. 2001). Rock samples directly derived from the mantle are more difficult to date because they do not contain zircon which is the mineral that is the most robust to metamorphism and alteration. A crustal section of Hadean mafic crust has been discovered in Northern Canada (Nuvvuagittuq Greenstone Belt) with the oldest units dated at 4.1 and 4.3 Ga (O'Neil et al. 2012). The 4.3 Ga age is still debated (Roth et al. 2013), but these findings suggest that the lower limit of the Hadean eon may have to be redefined. Indirect information on the chemical composition of the mantle and the chronology of the silicate differentiation is provided by radioactive systematics that record parent-daughter chemical fractionation. Noble gas systematics traces the mantle degassing, and the xenon isotope signature is consistent with extensive loss of volatile elements within the first 100 Ma of the Earth's history (Allègre et al. 1983; Yokochi and Marty 2005; Mukhopadhyay 2012). ^{142}Nd anomalies measured in Archean samples and the large Hf isotope variations measured in Hadean zircons and Archean rocks are undisputable evidences for early silicate differentiation events during the first 100–150 Ma of the Earth's history (Blichert-Toft et al. 1999; Boyet et al. 2003; Caro et al.

2003; Kemp et al. 2010; Rizo et al. 2011). These isotope signatures are explained by multiple generations of magma oceans during the accretion. The last important event of melting would be a direct consequence of the Moon-forming giant impact dated between 140 and 200 Ma (Maurice et al. 2020; Sio et al. 2020). The impact did not induce complete melting and homogenization of the whole terrestrial mantle, as isotopic signatures of pre-impact heterogeneity are preserved (Lock et al. 2020). Although during the Hadean, the mantle must have been hotter and the convection more vigorous, early chemical heterogeneities have been preserved from mantle mixing until the Archean. These results question the style of the Hadean mantle convection relative to its modern convection regime driven by plate tectonics.

surface) and equatorward flow near the surface. The Hadley circulation cells, one on each hemisphere, cover about half of the Earth’s surface area. The Hadley cells carry heat and moisture from the tropics to the northern and southern mid-latitudes. Hadley cells are also present on other terrestrial bodies like Mars, Titan, or Venus. On a slowly rotating planet like Venus, the Hadley circulation can extend almost to the poles. Circulation cells like the Hadley cells probably exist also on other rocky exoplanets and influence their climate substantially.

Definition

The Hadley cell on the Earth is a circulation pattern that dominates the tropical atmosphere, with rising motion near the equator, a compensatory sinking motion in the subtropics, poleward flow in the upper troposphere (7–20 km above the

History

Ernst Haeckel (1834–1919) was a German zoologist, great supporter of the evolution theory. He developed his own theory of evolution founded on Darwinism and also on some Lamarckian principles. His theoretical thought was closely connected to his monistic philosophical view.

Regarding the origin of life, he proposed a scenario of ► [abiogenesis](#) based on protoplasmic theory and claimed that evolution of matter could lead to a form of albuminoidal protoplasm. He called *Monera* the primitive entities coming before cells.

Haldane's Conception of Origins of Life

Stéphane Tirard

Centre François Viète d'Histoire des Sciences et des Techniques EA 1161, Faculté des Sciences et des Techniques de Nantes, Nantes, France

Keywords

Prebiotic soup

History

John Burdon Sanderson Haldane (1892–1964) was one of the famous British biochemists and geneticists of the first part of the twentieth century. He notably participated to the reflection about evolution questions, and he was one of the main actors on the synthesis of that issues.

During his career, he spoke several times about the problem of the origins of life; however, he never worked as specialist of the topic. He published a very important text on this matter in 1929, in *The Rationalist Annual*. This text is often presented as linked to the text of Aleksandr Ivanovich Oparin (1894–1980) (the Oparin's paper on origins of life was firstly published in Russian in 1924), and it is often said to be Oparin-Haldane's theory. However, these two papers were independently published.

Haldane gave a complete scenario describing primitive conditions on earth and steps of chemical evolution from mineral to organic molecules. The main reactions occurred in the primitive sea, sort of complex chemical solution, named *hot dilute soup* by Haldane.

His text began with a historical narrative about spontaneous generation and by an analysis of the nature of the bacteriophage, which he considered as “a step beyond the enzyme on the road of life, but it is perhaps an exaggeration to call it fully alive” (p. 106).

He suggested a complete scenario beginning with the primitive atmosphere contained little or no oxygen, but carbon dioxide, and claimed that ammonia could be formed by the action of water on nitride contained in the crust. Moreover, in the lack of ozone, ultraviolet rays could be chemically active. One of his most important suggestion is that “when ultraviolet light acts on a mixture of water, carbon dioxide, and ammonia, a vast variety of organic substances are made, including sugars and apparently some of the materials from which proteins are built.” He claimed that in the current nature, such a mixture would be eaten by microorganisms, but in the primitive conditions, in this “hot dilute soup,” big molecules could be synthesized. For him, “the first living or half-living thing” was capable of reproduction; in other words, they were the first genes (p. 107). Then he claimed that “when the whole sea was a vast chemical laboratory,” the condition for the formation of oily films and then primitive cells must have been favorable.

Haldane's proposal, with Oparin's one, revealed the evolution of ideas on the origin of life at the beginning of the twentieth century. Haldane, according to current biology, used his biochemist and geneticist view to describe the steps of a chemical process producing the most simple living beings.

Halley, Edmond

Fernando B. Figueiredo

CITEUC, University of Coimbra, Coimbra, Portugal

History

Edmund Halley (1656–1742) was a multifaceted English scientist, fellow of the Royal Society (1678) and Royal Astronomer (1720), which made significant contributions on mathematics, astronomy, navigation and geophysics. Halley's name will remain in history largely due to his work of 1705 on the motion of comets. The

similarity that he founded between the orbital elements for the comets seen in 1531, 1607, and 1682 led him to suggest that this comet, that same comet that would one day bear his name, would return in December 1758. In fact the comet was observed on 25 December 1758 (very slightly later than Halley expected).

Halley's work in astronomy is not restricted to the movement of comets. He made important works in stellar astronomy, having been the first to accurately cataloging the south sky hemisphere. And he was also the first to propose using transits of Mercury and Venus to determine the Earth-Sun distance and therefore the scale of the solar system. He was very interested also on the solution of the determination of longitude at sea. In geophysics Halley published charts of the variation of the compass of the north Atlantic ocean, giving the first charts with lines of equal magnetic declination plotted.

Among all his scientific contribution there one that worth mentioning, his commitment and enthusiasm in the publication of one of the fundamental works of modern science, the *Philosophiæ Naturalis Principia Mathematica* (1687), of his friend Isaac Newton (1643–1727).

Definition

A halogen is a chemical element from Group 17 (in the IUPAC convention) (formerly VII,

VIIA) of the periodic table, composed of fluorine, chlorine, bromine, iodine, and astatine. The man-made element 117 is predicted to be a halogen. The Swedish chemist Berzelius coined the term “halogen” from the Greek *hals*, “salt,” and *gen*, meaning “come to be” – for an element that produces a salt with a metal. The halogens are the only periodic table group that contains elements in all three familiar states of matter at standard temperature and pressure. At room temperature and pressure, fluorine and chlorine are gases, bromine is a liquid, and iodine and astatine are solids. The halogens show several trends as the atomic number increases, including decreasing electronegativity and reactivity and increasing melting and boiling points.

In their elemental form, the halogens exist as diatomic molecules, but these are relatively unstable. Due to their high reactivity and electron affinity, halogens are usually found in nature as molecular compounds or as ions. Halogen anions, known as halides (e.g., Cl^- , Br^- , and F^-), and oxoanions such as iodate (IO_3^-) are commonly found in many minerals and are major components of seawater. Halogenated organic compounds are also produced by living organisms. The halogens all form binary compounds with hydrogen, for example, HF, HCl, HBr, and HI, which are strong Brønsted-Lowry acids.

Halophile

Salt-loving organisms

Definition

Halophile is an organism that needs high salt concentrations for growth. A widely used definition is that of Kushner and Kamekura (1988) who classify organisms depending on the salt concentration needed for optimum growth. Thus, non-halophiles grow best in media containing less than 0.2 M salts, while halophiles grow best in media containing from 0.2 to 5.2 M dissolved salts. Halophiles can be further divided into slightly halophilic (optimum growth between 0.2 and 0.5 M salt), moderately halophilic (0.5–2.5 M salt), and extremely halophilic (above 2.5 M salt).

Overview

All three domains of life include halophilic microorganisms. Archaeal halophiles, all belonging to the *Euryarchaeota*, can be found among the methanogens and the members of the order *Halobacteriales* that only includes extreme halophiles. Within this order, there is a single family (the *Halobacteriaceae*) that includes 28 genera, some of them of alkaliphilic organisms. The most halophilic organism as well as the ones most frequently found in hypersaline environments is included within this family. Bacterial phyla such as *Cyanobacteria*, *Proteobacteria*, *Firmicutes*, *Actinobacteria*, *Spirochaetes*, and *Bacteroidetes* are also halophiles (Oren 2008). Finally, some eukaryotic organisms – plants, fungi, ciliates, and flagellates – are halophilic. The unicellular green alga *Dunaliella salina* is the most halophilic known eukaryote. Normally, every halophile has a relatively narrow range of salt concentration that allows growth. The proteobacterium *Halomonas* spp. is an exception, being able to grow over a very wide range of salt concentration.

Halophiles are usually found in phylogenetic trees that also include non-halophilic relatives, but three large phylogenetically coherent groups comprise only halophiles. Such is the case of the aerobic ► *Archaea* from the order *Halobacteriales* (also known as haloarchaea), the anaerobic fermentative ► *bacteria* from the order *Halanaerobiales*, and the *Gammaproteobacteria* from the family *Halomonadaceae*.

A group of phylogenetically related halophiles within the *Bacteroidetes* is recovered from hypersaline environments all over the world.

Halophilic microorganisms use two different strategies to cope with the osmotic stress stemming from the high ionic concentration of their environments. *Archaea* of the order *Halobacteriales*, anaerobic *Bacteria* of the order *Haloanaerobiales*, and some members of the *Bacteroidetes* (i.e., *Salinibacter ruber*) accumulate high concentrations of inorganic ions (mostly potassium) in the cytoplasm. These three groups include the most extreme halophiles. The so-called “salt-in” strategy requires an adaptation of the whole intracellular machinery to work in highly saline environments. All other halophilic organisms keep their osmotic balance by producing and/or accumulating “compatible” low-molecular-weight organic solutes (see “compatible solutes”) whose concentration is regulated according to the salinity of the environment.

Habitats for halophilic microorganisms include salt marshes, salt lakes that may be alkaline (Mono Lake, Wadi Natrun), or near neutral (e.g., the Dead Sea, Great Salt Lake, Tuz Lake, Chaka Lake, and some cold hypersaline lakes in the Antarctica), man-made salterns either coastal or inland, hypersaline deep sea masses, salted food, animal hides, saline soils, dessert salt crusts, and subterranean brines.

These environments have been classified depending on whether they originated through the evaporation of seawater or not, thus talassohaline (e.g., solar salterns) and athalassoaline (e.g., the Dead Sea).

Hypersaline environments are extreme habitats and very high salt is not the only condition restricting biodiversity in these systems. They can also have high pH or, depending on their geographical location, high or low temperatures. In addition, some hypersaline environments have very low nutrient availability or high concentrations of toxic compounds such as heavy metals. Accordingly, halophilic organisms may display additional extremophilisms. Alkaliphilic, psychrotrophic, and thermophilic halophiles have been described (for instance,

the thermophilic bacterium *Halothermothrix orenii*, the archaeon *Halorubrum lacusprofundi*, and members of the archaeal genus *Natronobacterium*).

Moderately halophilic bacteria inhabit hypersaline habitats with salinities around 10%. Aquatic environments with higher, near-saturation salt concentrations may be densely populated with extremely halophilic microorganisms, and this leads to bright red, orange, or purple colorations due to the pigments of these organisms. In some multipond solar salterns, microbial diversity is found to decrease at higher salinities. However, the number of microorganisms increases with salinity, reaching very high densities of up to 10^8 cells/ml at near-saturation concentrations. Most of these cells correspond to organisms of the *Archaea* domain although in some environments *Bacteria* can account for up to 30% of the total counts.

Hypersaline environments all over the world contain *Archaea* such as the square haloarchaeon *Haloquadratum walsbyi* and related populations, as well as *Halorubrum* representatives. In the *Bacteria* domain, the *Bacteroidetes* *Salinibacter* spp. and related phylotypes are frequently found in hypersaline settings close to saturation, although in some cases *Proteobacteria* constitute the bulk of extremely halophilic *Bacteria* detected in these systems. At near-saturation concentrations, both cell number and diversity of ▶ Eukarya decrease dramatically, leaving only *Dunaliella* and some extremely halophilic fungi in low numbers. At salinities above 10–15%, large organisms disappear, with the exception of the brine shrimp *Artemia salina* and the larvae of the fly *Ephydra*. Hypersaline environments harbor the highest numbers of viruses reported so far for aquatic systems.

Most dissimilatory prokaryotic metabolisms can function in hypersaline environments although a few of them have never been detected at salt concentrations above 10% (e.g., proton-reducing acetogens, methanogenesis from acetate, or autotrophic nitrite oxidations). For a detailed discussion of the energetics of halophilism, see Oren (1999).

In addition to their evolutive and ecological interest, halophilic microorganisms have some biotechnological applications. Haloarchaea produce bacteriorhodopsin that can be used as photo-active material in optical devices as well as polyhydroxyalcanoates, exopolysaccharides, and halocins. Moderately halophilic bacteria are used for the commercial production of their compatible solutes ectoines and hydroxyectoines, which find application in the cosmetic industry or the biological treatment of saline industrial waste effluents. Halophilic eukaryotes such as *Dunaliella* are used as a natural source of beta-carotene in cosmetics and some food while the shrimp *Artemia salina* can be used in aquaculture.

Halotolerance

Josefa Anton

Department of Physiology, Genetics and Microbiology, University of Alicante, Alicante, Spain

Keywords

Compatible solutes · Ionic stress · Salt

Synonyms

[Salt tolerance](#)

H

Definition

Halotolerance is tolerance to ionic stress or the ability of an organism to grow at salt concentrations higher than those required for growth. Halotolerant organisms are able to survive at high salt concentrations but do not require these conditions for growth.

Overview

Halotolerance is a relative term that refers to the ability to survive or thrive at salt concentrations higher than those necessary for growth. A microorganism is considered extremely halotolerant if its growth range extends above 2.5 M salt. A 0.9% NaCl would be considered an isotonic solution by most nonmarine and non-halophilic organisms. In nature, halotolerant organisms can be found in settings such as saline waters and soils that are inhabited by autochthonous halophilic microbiota or even in association with animals. Such is the case of microbiota such as *Staphylococcus* species that live on human skin. Because of their exposure to the salts in sweat, they are very halotolerant and they can also grow well at NaCl concentrations as high as 15%. However, they can also grow in the absence

of salt and are thus said to be halotolerant and not halophile. This property is exploited in the design of selective growth media. Halotolerant organisms have developed metabolic processes, such as the accumulation of compatible solutes that allow them to compensate the osmotic pressure and continue to live in hyperosmotic environments.

Salt tolerance can vary depending on nutritional or environmental factors such as pH, temperature, and redox potential. Since high salt has been traditionally used as a way of preserving food, halotolerant microorganisms can be a cause of spoilage of salt-preserved food.

The three domains of life include many examples of halotolerant microorganisms such as the ► [bacteria](#) of the genera *Alteromonas*, *Lactobacillus*, *Bacillus*, *Myxococcus*, and *Pediococcus*, as well as many cyanobacteria, some methanogenic and thermophilic archaea, and halotolerant fungi such as *Debaromyces*, *Hansenula*, *Cladosporium*, and *Saccharomyces*.

Synonyms

[High accuracy radial-velocity planet searcher](#)

Definition

HARPS is a high-resolution spectrograph designed to achieve long-term stability enabling Doppler velocity measurements at the level of 1 m/s, in order to derive radial-velocity orbits for stars orbited by planets as small as the Earth. It is presently the only instrument installed on the 3.6-m telescope at the European Southern Observatory on La Silla in Chile, where it will soon be

joined by the infrared spectrograph NIRPS. The spectrograph is fed by fibers and the optics are enclosed in a vacuum tank, to eliminate the effects of changes in the index of refraction at the echelle grating due to changes in the atmospheric pressure. The temperature of the instrument is stabilized at the level of 0.001 K, which is also critical for the velocity stability. The wavelength calibration was first provided by thorium-argon hollow cathode lamps; Fabry-Perot etalons and Laser Combs were later added as calibration sources. The calibration of the spectrograph is continuously undergoing improvements. HARPS has demonstrated the potential to reach a velocity precision of perhaps 20 cm/s. HARPS and ► [HIRES](#) on Keck 1 in Hawaii are premier instruments for determining the masses of small planets. The data from these two telescopes have been used to detect several potentially habitable planets around stars GJ 667C and Gliese 581. A copy of HARPS, called HARPS-North or HARPS-N, for use in the northern hemisphere is also in function since 2012. Since 2017, ESPRESSO, a new spectrograph installed on the VLT in Paranal has been able to reach even better precisions.

Definition

► [Hayabusa](#) (meaning peregrine falcon) space missions have been developed by JAXA to explore near-Earth asteroids and collect samples thereof.

Launched in May 2003, the first Hayabusa spacecraft begun its rendezvous with stony asteroid (25143) Itokawa in September 2005. After 2 months of observations, it collected dust samples on its surface. The return capsule departed in April 2007, landed safely in Australia in June 2010, and was transferred to the Japanese curation facility.

Launched in December 2014, Hayabusa2 spacecraft begun its rendezvous with carbonaceous asteroid (162173) [Ryugu](#) in June 2018. After observing its surface and releasing rovers, it collected samples. The spacecraft departed in November 2019 and released its return capsule in December 2020 in Australia. Preliminary curatorial work on the samples takes place in Japan.

Overview

The first Hayabusa spacecraft carried four scientific instruments, AMICA camera, NIRS spectrometer, LiDAR laser instrument, and XRS X-ray spectrometer. Besides its return capsule, it embarked navigational instruments and tested new technical developments. The total mass, including propellant for chemical propulsion and xenon for electrical propulsion was ≈ 530 kg.

This complex mission faced major issues. After the launch from Japan, it was hit by a solar flare that damaged the solar cells, reducing the electrical power and the efficiency of the ion engines. At the end of the characterization phase, Hayabusa released the MINERVA micro-lander, which escaped Itokawa gravitational pull. After having deployed its sampling horn to collect asteroidal dust and sealed it, the spacecraft attempted twice to touch down on the surface of the asteroid.

Hayabusa mission, the first one to bring back asteroidal samples on Earth, was nevertheless most successful. Asteroid Itokawa looks like a contact binary and is quite small (major axes 530 m, 290 m, 210 m). It is rather porous (density $\approx 1930 \text{ kg m}^{-3}$) and could be built from loose-packed rocks held together by gravity, after an impact on a larger parent-body. The topography is varied, with boulders on rough terrains and a featureless central area of fine dust particles forming a smooth regolith in gravitational lows. Such results are of importance when considering orbital deflection techniques, to be implemented if a similar asteroid was discovered on a collision course with the Earth.

Samples analyses have identified more than 1000 dust particles from Itokawa, with sizes mostly below 100 micrometers. They present, as ordinary chondrites, mostly minerals (olivine, pyroxene, plagioclase, troilite) and a low organics content.

Hayabusa2 spacecraft is an upgraded version of the first Hayabusa, with a mass of 610 kg. It typically carried cameras, an IR spectrometer, a LIDAR, together with instruments for navigation, and four rovers to scientifically explore the surface, rovers 1A, 1B, 2 from JAXA, as well as rover MASCOT from DLR and CNES.

This outstanding mission required elaborate studies to select appropriate landing and sampling sites on Ryugu. Mini-rovers 1A and 1B were successfully deployed in 2018 and hopped as expected on the surface. MASCOT rover (with instruments including a camera and an IR spectral microscope) was also deployed in 2018. Rover-2 could unfortunately only perform orbital gravitational measurements before crashing down into the asteroid in 2019.

Asteroid Ryugu has a round shape with an equatorial bulge, typical of a pile of loose rocks, formed by re-accumulation of rubble ejected by impact from a larger asteroid. Its size is about 865 m and it is highly porous (density $\approx 1200 \text{ kg m}^{-3}$). On its rather dark surface (geometric albedo from 0.4 to 0.8), irregularly distributed craters and fluffy boulders have been discovered, as well as color variations, possibly related to previous orbital changes. Most interestingly, Hayabusa2 has revealed significant amounts of organic molecules and hydrated minerals.

Last but not the least, samples have been successfully collected. Surface samples were collected in February 2019. Samples from the subsurface were collected in July 2019, after an impact experiment created an artificial crater of ≈ 10 m. Both sets, corresponding to a total mass about 5.4 g, were stored in separate containers inside the return capsule.

Preliminary analyses of the samples in Japan confirm similarities with CI chondrites. They will be developed in selected worldwide laboratories in 2022, to elucidate water-organics interactions and the evolution of organic matter in the Solar System. Meanwhile, the successful Hayabusa2 mission has been extended, with an expected flyby of an unusual L-type asteroid in July 2026 and rendezvous with a very small (size ≈ 30 m) asteroid in July 2031.

Synonyms

Protonated tricarbon monoxide

Chemical Formula

Definition

The ion HC₃O⁺ is the protonated form of tricarbon monoxide (C₃O). It has been identified in the cold dark cloud TMC-1, where other protonated molecules have been also observed (Cernicharo et al. 2020). The ion HC₃O⁺ can be formed in cold dark clouds by proton transfer of other abundant cations like HCO⁺ and H₃⁺, a process which is exothermic due to the high proton affinity of C₃O, 885 ± 5 kJ mol^{−1} (Botschwina 1989). The dipole moment of HC₃O⁺ is calculated to be 3.41 Debye (Cernicharo et al. 2020).

HC₄NC

Marcelino Agúndez
Instituto de Física Fundamental, CSIC, Madrid,
Spain

Chemical Formula

Definition

The molecule HC₄NC is a metastable isomer of cyanodiacetylene (HC₅N), which lies 113.8 kJ mol^{−1} above HC₅N (Botschwina et al. 1998). It was detected for the first time in space in the cold dark cloud TMC-1 (Xue et al. 2020; Cernicharo et al. 2020). This species belongs to the family of isocyanopolyyne HC_{2n}NC (with $n = 1, 2, 3, \dots$), which are metastable isomers of cyanopolyyne HC_{2n}CN. Isocyanopolyyne are less abundant than cyanopolyyne in TMC-1 by factors of 45–77 for HC₂NC and 200–600 for HC₄NC (Xue et al. 2020; Cernicharo et al. 2020). The larger member of the family HC₆NC has not yet been detected.

Chemical Formula

HC₅NH⁺

Definition

The ion HC₅NH⁺ is the protonated form of cyanodiacetylene (HC₅N). It has been tentatively identified in the cold dark cloud TMC-1, where other protonated molecules have been also observed (Marcelino et al. 2020). The assignment is based on high-level ab initio calculations together with some astrophysical arguments. The ion HC₅NH⁺ can be formed in cold dark clouds by proton transfer of other abundant cations like HCO⁺ and H₃⁺, a process which is exothermic due to the high proton affinity of HC₅N, 770 ± 20 kJ mol^{−1} (Edwards et al. 2009). The dipole moment of HC₅NH⁺ is calculated to be 3.26 Debye (Marcelino et al. 2020).

Definition

► **Hydrogen cyanide** polymers – i.e., heterogeneous solids formed upon spontaneous polymerization of HCN – are likely to have been among the first macromolecules on prebiotic Earth.

Overview

Hydrogen cyanide (HCN) polymerizes spontaneously in the neat liquid and in solution. Due to the abundance of hydrogen cyanide in the Universe (Debes et al. 2008), the potential role of hydrogen cyanide polymers in astrochemistry and the origin of life has provoked much speculation. Gas phase HCN is found both in interstellar molecular clouds and in comets in the solar system.

The ► **oligomerization** of HCN was first observed by Proust (1806), and analyses of the

soluble fraction date back to the late 1800s and early 1900s (Lange 1863; Wippermann 1874; Bedel 1923). Volker was the first to propose a structure for the insoluble ► **polymer** in 1960, a so-called “ladder” structure formed by repeats of the HCN dimer in the *trans* configuration (Volker 1960). The *cis* variation was subsequently offered by Umemoto et al. (1987). A more provocative model, from the standpoint of the origins of life, was suggested by Matthews, based on the observation of α -amino acids in polymer hydrolyzates; polymerization was proposed to occur via the HCN trimer aminomalononitrile and result in a structure with a -NCC- backbone that would form ► **polypeptide** upon contact with water (Matthews et al. 1977). However, Ferris has argued that the HCN tetramer, diaminomaleonitrile (DAMN), must be the “direct precursor” to HCN polymers, since dimers and trimers are not expected to accumulate (Ferris et al. 1981).

The above structures have been found to be inconsistent with recently acquired ¹³C and ¹⁵N solid state NMR spectra of polymers formed in neat HCN. These data suggest that the polymers are formed by simple monomer addition, first in head-to-tail fashion to form linear, conjugated chains, and then laterally to form saturated two-dimensional networks (Mamajanov and Herzfeld 2009a). This interpretation of the NMR spectra finds support in other information about the polymerization of neat HCN, including the presence of free radicals (Budil et al. 2003) and the fragmentation pattern in a ► **GC/MS** chemolysis study (Minard et al. 1998) (Fig. 1).

A different kind of HCN polymer has been shown to form upon mild heating of DAMN. ¹³C and ¹⁵N solid state NMR spectra, as well as the optical properties and electrical conductivity of the product, are consistent with an HCN trimer repeat unit. However, rather than forming a protopeptide, the subunits cyclize to form poly-[aminoimidazole] (Mamajanov and Herzfeld 2009b).

Despite extensive effort, there is no scientific consensus concerning the potential role of the HCN polymer in prebiotic evolution.

Keywords

Isomer

Synonyms

Cyanic acid; Fulminic acid; Isocyanic acid;
Isofulminic acid

Definition

HCNO isomers are molecules having the same empirical formula (HCNO) but a different connectivity. These isomers cannot be transformed from one to another without breaking a bond.

History

About 1825, Liebig and Gay-Lussac found out that silver fulminate had the same empirical

formula as a compound called silver cyanate (more correctly referred to as silver isocyanate), which Wöhler had analyzed about a year earlier. The two compounds were clearly different and thus led to the concept of isomerism.

Overview

To date, four molecules are known with the empirical formula HCNO. The lowest-energy form is isocyanic acid, $\text{H}-\text{N}=\text{C}=\text{O}$; cyanic acid, $\text{H}-\text{O}-\text{C}\equiv\text{N}$, is somewhat higher in energy (103.2 kJ/mol); fulminic acid, $\text{H}-\text{C}\equiv\text{N}-\text{O}$, is considerably higher (295.9 kJ/mol); and iso-fulminic acid, $\text{H}-\text{O}-\text{N}\equiv\text{C}$, is higher still (352.2 kJ/mol). Fulminic acid is a linear molecule; the others are all planar with the heavy atoms being nearly linear and the H atom bent trans to the heavy atom chain. A review of their structural and spectroscopic properties and their energetics was given by Teles et al. (1989). More recently, high-level quantum chemical calculations of the energies have been performed by Schuurman et al. (2004).

Single-crystal X-ray crystallography has shown that solid salts considered to be cyanates are generally much better described as isocyanates. Consequently, adding strong acids to these salts releases isocyanic acid (HNCO), without clear evidence of formation of cyanic acid (HOCN). HNCO was prepared in its pure form in the nineteenth century. In contrast, it appears as if HOCN can only be generated in situ. Interestingly, even though fulminic acid is much higher in energy than cyanic acid, it is possible to prepare HCNO in its pure form. Again, iso-fulminic acid has to be generated in situ.

Rotational spectra of all four isomers have been measured. Not surprisingly, iso-fulminic acid was the last detected (Mladenović et al. 2009). While HNCO was detected in space in 1972, HCNO and HOCN were only detected very recently (see Brünken et al. 2010).

HNCO can trimerize to cyanuric acid, a six-membered ring with alternating C and N atoms.

The anion NCO^- is neither well described as isocyanate with the negative charge at the N atom

nor as cyanate with the negative charge at the O atom. Instead, the charge is delocalized to essentially equal amounts over both atoms. Thus, the CO bond has a formal bond order of 1.5 while that of the CN bond is 2.5. An infrared feature at 4.62 μm , observed in interstellar ices, coincides with the strong asymmetric stretching mode of the NCO^- anion and has been attributed to this species. Unfortunately, features in solid-state spectra are not particularly specific. As a consequence, the assignment may well be correct but is by no means certain.

Of the four isomers, the three lower-energy ones have been detected in the [▶ interstellar medium](#): HNCO, HCNO, and HOCN.

Keywords

Planetary atmosphere · Transiting planet

Definition

HD 189733b is a transiting [▶ Hot Jupiter](#) that is especially well suited for studies of its atmosphere. Spectroscopic observations with the Hubble Space Telescope and [▶ Spitzer Space Telescope](#) have revealed the presence of molecules such as water vapor and methane (Fig. 1).

History

Early results from radial-velocity surveys suggested that gas giant exoplanets were being found more frequently around stars with higher concentrations of heavy elements in their atmospheres than the Sun (e.g., see Santos et al. 2001; Fischer and Valenti 2005). This motivated some teams to search for planets around samples of metal-rich stars using radial velocities and then to look for transits with follow-up photometry. One of these efforts, the ELODIE metallicity-biased search for transiting Hot Jupiters (da Silva et al. 2006), announced the discovery of HD 189733b (Bouchy et al. 2005). This planet proved to be especially well suited for follow-up studies of its atmosphere because it is in a tight orbit around a nearby star that is somewhat cooler

HD 189733b, Fig. 1 The light curve of HD 189733 observed with the Infrared Array Camera on the Spitzer space telescope at $8\ \mu\text{m}$. More than half the orbit is covered. The deep event at phase 0.0 is the transit of the planet in front of the star. The shallower event at phase 0.5 is the secondary eclipse when the planet passes behind the star and its thermal emission is blocked. The depth of the

secondary eclipse indicates that 0.34% of the total radiation of the system at $8\ \mu\text{m}$ arises from the planet. This sets the planet's dayside temperature at 1212 K. The emission increases slowly with phase as the planet moves around in its orbit and more of the dayside comes into view. **(b)** Provides an expanded view of the upper portion of **(a)**

than the Sun, thus producing a favorable contrast between the emission from the planet compared to the star (Fig. 2).

Overview

The parent star HD 189733 is significantly cooler than the Sun, with an effective temperature of 4980 K, corresponding to an early K [spectral type](#). The distance to the star is only 19.3 pc, which makes it quite bright, with an apparent visual magnitude of 7.67. The period of the circular orbit is only 2.2186 days long, and thus the planet is strongly heated by the incident radiation

from the star. These factors all combine to make HD 189733b especially well suited for follow-up observations of the thermal emission from the planet's atmosphere. Deming et al. (2006) first reported the detection of secondary eclipses, using the *Spitzer Space Telescope* at $16\ \mu\text{m}$ to measure a drop of 0.55% in the total thermal emission when the planet disappears behind the star. Subsequently, Knutson et al. (2008) monitored the emission at $8\ \mu\text{m}$ over more than half the orbit and showed that the dayside temperature is 1212 K, and the nightside is only 239 K cooler. This implies efficient heat transfer from the day-side to the nightside and thus dramatic weather in the atmosphere of HD 189733b.

HD 189733b, Fig. 2 The observed spectrum (*black triangles*) and two theoretical spectra of the predominantly molecular hydrogen atmosphere, showing the effects of small amounts of water (*blue*) and methane in combination with water (*orange*). The measured spectrum exhibits significant differences at 1.7–1.8 μm and at 2.15–2.4 μm from what is expected due to water vapor alone. These

departures are interpreted as additional absorption features due to the presence of one or more other species in addition to water. When considering only water and methane, the theoretical spectrum best fitting the data was determined by binning the model (shown as *white crosses*) to the spectral resolution of the observations (Swain et al. 2008)

Spectroscopy of the wavelength dependence of the transit depth in the near infrared with the NICMOS instrument on the *Hubble Space Telescope* by Swain et al. (2008) gave dramatic confirmation for the earlier preliminary reports of the detection of water vapor in the H_2 -dominated atmosphere of HD 189733b and suggested in addition the detection of methane. This was later confirmed by McCullough et al. (2014). Subsequent NICMOS spectroscopy of secondary eclipses added carbon monoxide and carbon dioxide to the list of proposed molecular detections (e.g., Swain et al. 2009).

Transiting planet

Definition

HD 209458b was the first exoplanet observed to transit its host star.

History

Arguments based on simple geometry predict that about one out of ten planets orbiting stars similar to the Sun should be seen to ► [transit](#) their parent star if the orbital period is only a few days. HD 209458 was roughly the tenth star to show a radial-velocity orbit implying a possible Hot Jupiter companion, so the discovery that the unseen companion transited the star came right on schedule. Follow-up photometry at times predicted for transits by the spectroscopic orbit with period 3.5247 days revealed dips in the light curve consistent with a ► [gas giant planet](#) 1.32 times the radius and 0.64 times the mass of Jupiter. For the first time it was possible to show that the bulk density of a Hot Jupiter was approximately as expected for a gas giant planet. This left little doubt that the growing population of radial-velocity planet candidates, in the early days of detecting extrasolar planets, must in fact be planets.

The discovery of HD 209458b transits is another example of simultaneity in science. Discovery papers from two independent teams were published simultaneously and back-to-back in the same issue of the *Astrophysical Journal Letters* (Charbonneau et al. 2000; Henry et al. 2000). The two teams based their transit time predictions on

radial velocities measured independently with ► [HIRES](#) on the Keck I telescope and Elodie on the 1.9-m telescope at the Observatoire de Haute Provence. The follow-up photometry was accomplished with small telescopes, in the case of Charbonneau et al. (2000) using a 4-in lens and ► [CCD](#) camera located in the parking lot of the High Altitude Observatory in Boulder, Colorado. Subsequent observations of transits with the STIS instrument on the *Hubble Space Telescope* illustrated (Fig. 1) the spectacular quality of light curve that could be achieved with a large telescope in space (Brown et al. 2001).

Overview

HD 209458 is a star very similar to the Sun in almost all respects. Because it is relatively nearby, only 47 pc from the Sun, it has the relatively bright apparent visual magnitude of 7.65. This makes it especially attractive for follow-up observations, such as spectroscopy of the atmosphere of the planet HD 209458b, although the planetary candidate ► [HD 189733b](#) is somewhat better in this regard because its host star is cooler. The same STIS spectra that yielded the spectacular light curve when integrated over all the available wavelengths (Brown et al. 2001) were subsequently reanalyzed at much finer spectral resolution, showing the presence of sodium in the planet's atmosphere (Charbonneau et al. 2002). This was the first detection of the atmosphere of an exoplanet. Subsequently, hydrogen was detected by Vidal-Madjar et al. (2003), sodium by Snellen et al. (2008), potassium by Keles et al. (2019), and helium by Alonso-Floriano et al. (2019). Some of these discoveries (e.g., sodium) were challenged in Casasayas-Barris et al. (2021) using ESPRESSO data. Additionally, Giacobbe et al. (2021) confirmed the discovery of different species like water vapor and carbon monoxide, and even confirmed the tentative detection of hydrogen cyanide (HCN) of Hawker et al. (2018). This is the first clear detection of a nitrogen bearing molecule in the atmosphere of an exoplanet. They also detected other molecules such as ammonia (NH₃), methane (CH₄), and acetylene (C₂H₂).

HD 209458b, Fig. 1 The light curve for the transit of HD 209458b obtained with the STIS instrument on the *Hubble Space Telescope*. Observations from several orbits were combined to produce full phase coverage of the transit light curve (Brown et al. 2001)

H

Although the bulk density of HD 209458b matches more or less the predictions of models for gas giant planets, the density is somewhat lower than expected. Apparently, the radius of the planet is expanded compared to those predicted by the models. For a while, HD 209458b was anomalous in this regard, but as more transiting Hot Jupiters were discovered, additional examples of inflated gas giants were identified. Although a number of possible physical mechanisms for inflating the radii of these planets have been suggested, the phenomenon remains puzzling.

Keywords

Radioactive heating · Heat transfer

Synonyms

[Geothermal flux](#); [Heat flux](#)

Definition

The heat flow in the most general sense is the rate of heat transfer per unit area across a given surface. The heat transfer mechanism could be radiation, convection, or conduction. It is measured in W m^{-2} . In geophysics and in planetary geophysics, the surface heat flow is more narrowly defined as the heat conducted through the ► [crust](#) across the planetary surface. In the (older) geophysical literature, the heat flow unit (hfu) is sometimes used, with $1 \text{ hfu} = 10^{-6} \text{ cal cm}^{-2} \text{ s}^{-1} = 41.84 \text{ mW m}^{-2}$.

Overview

Heat is generated in the interior of planets and satellites by the decay of radioactive elements, by exothermic phase transitions and chemical reactions, and by the dissipation of mechanical energy upon, for example, planetary contraction or differentiation and tidal deformation. The rate of heat loss of a ► [planet](#) or satellite provides constraints on the amount of heat being produced in the planet and the temperature distribution in the interior. The heat loss can – in principle – be measured from space with infrared radiometers as the heat radiated by the planet. The latter quantity is also called the planet’s intrinsic ► [luminosity](#) (similar to the luminosity of a ► [star](#)). In the inner solar system, however, the luminosity is dominated by the solar heat that is absorbed in the atmosphere and in the surface ► [rock](#) and radiated back into space. (The contribution by the reflected sunlight can be separated in the electromagnetic spectrum.) Therefore, the heat flow out of the interior of a ► [terrestrial planet](#) must be measured at a depth where perturbations due to the solar radiation and thermal perturbations in the atmosphere are sufficiently small. This depth is a few times the thermal skin depth $\sqrt{\frac{\kappa\tau}{\pi}}$ with κ the thermal diffusivity and τ the period of the thermal perturbation. The period τ ranges from a planetary day (or ► [sol](#)) to centuries if climatic effects are taken into account. Usually, a depth of a few meters will be sufficient but depending on the required accuracy. Measuring the heat flow then requires measuring both the thermal conductivity and the temperature gradient. Many heat flow measurements have been made on the ► [Earth](#), and heat flow maps have been compiled (e.g., Pollack et al. 1993; see also Jaupart and Mareschall 2015 for a review). The variation of the heat flow reflects volcanic and orogenic provinces and chains where heat flow is high and thick continental shields where heat flow is low. The average value is 84 W m^{-2} , and the variation is between a few tens to a few hundreds mW m^{-2} . Heat flow has been measured on the Moon at two sites by the Apollo missions. The values are 12 and 21 mW m^{-2} (Langseth et al. 1976; Warren

and Rassmussen 1987). These values are still subject of debate. A recent review can be found in Siegler and Smrekar (2014). No other planetary heat flow values are available, but heat flow measurements have been repeatedly proposed (e.g., Spohn et al. 2001).

In the outer solar system, the intrinsic luminosities of ► Jupiter, ► Saturn, ► Uranus, and ► Neptune have been measured. These are 5.44 ± 0.43 , 2.01 ± 0.14 , 0.042 ± 0.047 (but not smaller than 0), and $0.433 \pm 0.046 \text{ W m}^{-2}$, respectively (e.g., Guillot and Gautier 2015 for a review). Dissipation of gravitational energy released upon contraction is the major source of heat in the interior of Jupiter. The heat flow value for the other ► giant planets, in particular, the difference in heat flow between Uranus and Neptune, is not well understood. The intrinsic luminosity of the Jovian satellite ► Io has been measured to be about 2 W m^{-2} (Spencer et al. 2000). It is widely agreed that the heat is due to tidal dissipation (compare Tides).

Heat Shock

J. Andy Spry
SETI Institute, Mountain View, CA, USA

Definition

The term “heat shock” describes a rapidly imposed, short duration heat treatment deployed to control microorganisms. For ► planetary protection and microbiology, this technique is used in enumerating spores, generally in a liquid sample. A combination of high temperature with a short exposure time (i.e., 80 °C for 10 min) kills the vegetative forms of mesophilic ► bacteria, leaving only mesophilic and thermophilic spores remaining viable in the sample. This is because, with such rapid timing, the vegetative

microorganisms do not have enough time to form new spores and are inactivated. When cooled, the liquid solution is spread on nutrient media and incubated to persuade spores remaining in the sample to grow and form colonies. The result of this standardized assay represents an estimate of the number of spores which were present in the original sample.

Definition

Heat is transferred in planetary and satellite interiors and atmospheres from regions of high temperature to regions of lower temperature. The heat transfer mechanisms are heat conduction, convection, and radiation.

Overview

In planetary interiors, heat is generated by the decay of the ► [radiogenic isotopes](#) ²³⁵U, ²³⁸U,

²³⁷Th, and ⁴⁰K. In addition, latent heat may be released and consumed through phase transitions, including melting and crystallization. The dissipation of kinetic energy of ► [planetesimals](#) colliding with the protoplanets during planetary accretion has heated the planetary interiors, in some cases up to the melting temperatures of their outer layers. The formation of the cores in terrestrial planets through differentiation has further heated the deep interiors. Since planetary surfaces are colder – their temperature being determined by the rate of solar radiation and the atmosphere ► [greenhouse effect](#) – heat is transferred to these surfaces from the deep interior. The resulting flow of heat may be associated with the conversion of heat into mechanical work and the conversion of heat into ► [magnetic field](#) energy. Moreover, the cooling may result in planetary contraction. The dominant heat transfer mechanisms in planetary interiors are heat conduction and convection (for a discussion of heat transfer in planetary interiors, see, e.g., Schubert et al. 2001).

In a typical substantial planetary atmosphere, heat is transferred by convection or radiation in the lower atmosphere (more specifically, the ► [troposphere](#) and ► [stratosphere](#)) and heat conduction and radiation in the upper atmosphere (more specifically, the ► [mesosphere](#) and ► [thermosphere](#)). The pressure level at the radiative-convective boundary (the tropopause) in the lower atmosphere depends on the composition of the atmosphere and the ► [opacity](#) of the major atmospheric constituents. Above this level (i.e., at lower pressures), the outgoing energy is transported by radiation until heat conduction becomes important. The radiative-convective boundary occurs when the atmosphere becomes optically thin to thermal radiation. Usually, this translates into a column optical depth, τ , approximately equal to unity. For τ approximately equal to unity or larger, the atmosphere is opaque, and the radiative energy is reabsorbed by the surrounding media, hence convection is the dominant form of heat transfer. For τ smaller than unity, the atmosphere is transparent and does not absorb efficiently.

Heat conduction. In gases, heat is conducted via the ► [diffusion](#) of molecules. Molecules with

high kinetic energy diffuse from regions of high temperature to regions of lower temperature. Interaction between molecules transfers energy and thereby heat. In solids, energy is transferred via lattice vibrations. In a perfect solid, vibrational energy would travel with sound speed, and heat would be rapidly dissipated. Imperfections in the solid slow the process of energy transfer, such that heat flows analogous to the diffusion of matter. The lattice model of conductive heat transfer thus associates vibrational energy with particles called phonons (it can be shown that vibrational energy must be quantized). The transfer of heat can then be modeled as diffusion in the phonon gas similar to diffusion in a real gas. The thermal conductivity varies with the lattice properties of the solid.

In planetary atmospheres, heat conduction is largely unimportant (except for the uppermost layers) with convection and radiation being more efficient heat transfer mechanisms. In planetary interiors, heat is conducted in regions that are immobile on planetary timescales of $>10^5$ years. One example layer is the stagnant ► **lithosphere** of planets such as ► **Mars**. On ► **Earth** where the lithosphere is broken up in plates that move laterally, vertical heat transfer through the plate is still conductive, while lateral heat transfer is mostly convective, depending on the plate speed. Other prominent layers of conductive heat transfer are

the boundary layers of mantle convection (compare Fig. 1 below and Schubert et al. 2001).

Mathematically, the (conductive) flow of heat $\vec{F}$ can be described by.

$$\vec{F} = -k\nabla T \quad (1)$$

where ∇T is the temperature gradient and k is the thermal conductivity. $\vec{F}$ is a vector quantity having a value and a direction.

The thermal conductivity can be both a function of pressure and temperature. In porous media, the thermal conductivity varies with the porosity and with the properties of any gas or fluid in the pores.

Radiation. Radiation is a heat transfer mechanism in regions that are transparent to electromagnetic waves and is particularly important in planetary atmospheres (see radiation in planetary atmospheres and Thomas and Stamnes 1999) and in stellar interiors (e.g., Hansen et al. 2012). For the highly absorbing planetary interiors, radiation is usually integrated into the mechanism of heat conduction, thereby increasing the thermal conductivity at high temperatures.

Convection. Thermal convection is a consequence of thermal expansion, with the density of gases and fluids decreasing with increasing

H

Heat Transfer, Planetary, Fig. 1 Color-coded temperature distributions in stagnant lid (a) and mobile lid convection (b) for strongly temperature-dependent viscosity after numerical calculations by Stein and Hansen (2008). Blue indicates low temperatures and red high temperatures. In stagnant lid convection, the flow is confined to occur

underneath a cold near-surface stagnant layer. In the stagnant layer, heat is transferred by conduction. In mobile lid convection, the cold near-surface layer participates in the convection. Arrows indicate the direction of flow. Mobile lid convection is a mode of convection largely analogous to plate tectonics (Courtesy of C. Stein and U. Hansen)

temperature. On time scales of millions of years, even solids such as rock in planetary mantles can be considered as extremely viscous fluids (► [Rheology \(Planetary Interior\)](#)). Consider a layer of fluid (or gas) sandwiched between a hot plate at the bottom and a cold plate at the top. Fluid near the hot plate will absorb energy, and its temperature will rise. As a consequence of the density decreasing with temperature, the fluid will become increasingly buoyant with respect to the colder fluid above and eventually will rise if the buoyancy is large enough to overcome inertia and internal friction. As it rises, it will transport heat that it may exchange with the fluid through which it rises and – in particular – it transfers heat to the cold top plate. The heat transfer is thus from the hot to the cold plate. In a similar thought experiment, heat can be generated within the fluid, cause buoyancy, and again be transported to the cold plate. The above is – in principle – the mechanism of heat transfer from the hot core through the mantle to the cold planetary surface and the mechanism of the transfer of heat generated in the interior of the planet to the same cold surface. It is the same mechanism of heat transfer from the interior of the hot core to the (colder) core-mantle boundary and from the warm surface of the planet to the colder regions in the atmosphere. In the atmosphere, convection includes large- and small-scale rising and sinking of air masses and smaller air parcels. These vertical motions effectively distribute heat and moisture throughout the atmospheric column. The mechanism also applies in the interiors of ► [giant planets](#) and in oceans. It is termed free convection because the flow is not driven by external forces. Forced convection in planets may be driven by, e.g., tides, ► [planetary](#), and in the atmosphere by variations in solar irradiation. The convective flow of heat $\vec{F}$ across a surface in a fluid is given by.

$$\vec{F} = \nabla \cdot \vec{u} \rho c_p T \quad (2)$$

where $\vec{u}$ is the velocity vector, ρ is the local density, and c_p the heat capacity at constant pressure.

Heat transfer by free convection can be characterized by a set of dimensionless parameters. The first and most important is the Rayleigh number Ra . For fluids heated from below, it is defined as.

$$Ra \equiv \frac{g \alpha \Delta T d^3}{\nu \kappa} \quad (3)$$

In addition to already defined quantities, g is the acceleration due to gravity, α is the thermal expansion coefficient, ΔT is the temperature difference between the top and bottom boundary, d is the layer thickness, ν is the kinematic ► [viscosity](#), and κ is the thermal diffusivity. The thermal diffusivity is related to the thermal conductivity, density, and heat capacity as follows: $\kappa = k/\rho c_p$. For internally heated fluids, ΔT is replaced with Qd^2/k , where Q is the heat production rate per unit volume. The term $g \alpha \Delta T$ in the nominator of Eq. 3 measures the thermal buoyancy. Note that there are two diffusivities in the denominator. The thermal diffusivity κ measures the loss of buoyancy due to thermal conduction, and the kinematic viscosity ν – the momentum diffusivity – measures the deceleration of the fluid due to momentum diffusion.

The steady-state heat transfer rate by convection through a fluid heated from below is measured by the Nusselt number Nu .

$$Nu \equiv \frac{qd}{k\Delta T} \quad (4)$$

with q the heat flow across the top surface. The Nusselt number is the ratio between the surface heat flow q and the heat flow that would be transferred by conduction $k\Delta T/d$. Since convection is an instability that sets in when the heat can be more efficiently transferred by convection, $Nu \geq 1$. In a fluid heated from within, the surface heat flow in the steady state equals Qd , and the Nusselt number as defined above is always unity. The efficiency of convective heat transfer is then measured by the value of the internal temperature: the lower the temperature at which the convection is operating, the more efficient is the internally heated convection.

Experiments with fluids and numerical solutions of the field equations of fluid mechanics show that there is a power law relationship between the Nu and the Ra numbers.

$$Nu = \left(\frac{Ra}{Ra_{crit}} \right)^\beta \quad (5)$$

where Ra_{crit} is the critical Rayleigh number for the onset of convection and β is a constant, the value of which is between 0.2 and 0.33 depending on boundary conditions and the temperature and pressure dependence of material properties. Similarly, for internally heated convection,

$$\theta \equiv \frac{kT}{Qd^2} = \left(\frac{Ra}{Ra_{crit}} \right)^\gamma \quad (6)$$

where T is the internal temperature and γ is between 0.2 and 0.25.

The parameters α , ν , and κ are pressure and temperature dependent. Of particular importance for planetary mantles – as numerical calculations and laboratory experiments have shown – is the pressure and temperature dependence of the viscosity (see ► [Rheology, Planetary Interior](#) for a discussion). Note that the solid mantles of terrestrial planets and satellites can be regarded as extremely viscous fluids for processes operating on geological timescales (i.e., on timescales of millions of years or more). The extremely large viscosity in the mantle causes inertia forces (such as the Coriolis force) to be negligible and the flow to be laminar, although at very large Rayleigh numbers, the flow tends to become increasingly chaotic (see, e.g., Ricard 2007). Within a ► [planetary interior](#), and in particular through the lithosphere, the outer boundary layer of the planet, the viscosity may vary over many orders of magnitude. A strongly temperature-dependent viscosity can result in the formation of a stagnant lid (compare Fig. 1). The pressure dependence can be speculated to lead to a second stagnant layer in the deep interior of the planet (e.g., Stamenkovic et al. 2012). The formation of a mobile lid requires the variation of the viscosity to be sufficiently small. The formation of a platelike mobile lid

(the fluid dynamical representation of ► [plate tectonics](#)) may require a viscoelastic rheology in which the yield strength may matter (compare Fig. 2). But it is not completely understood how plate tectonics on the Earth works and what the exact conditions for the stability of plate tectonics are. The latter makes it, of course, difficult to predict plate tectonics on other planets.

While the viscosity and its dependence on pressure and temperature is thought to be a most important parameter for mantle convection, viscosity is of little importance for convection in the planetary atmosphere and the core and in the interiors of the giant planets. In these, inertia forces, in particular the Coriolis force, matter and the flow is mostly turbulent. The Coriolis force provides helicity (corkscrew-like motion) for the flow in the core which is a prerequisite for dynamo action. In the atmosphere, the Coriolis force causes the vortices that dominate the weather system on, e.g., the Earth. In the giant planets, the Coriolis force is again taken to be the reason for the observed vortices (see ► [Jupiter](#)).

An additional heat transport mechanism that may occur on stagnant-lid planets with significant extrusive volcanic activity is heat piping (O'Reilly and Davies 1981). Melt from the interior rises through channels and volcanic pipes and erupts at the surface. The melt ascending through the lithosphere and crust transports heat from the base of the lithosphere to the surface, where the resulting volcanic load may push cold lithospheric material downward, efficiently cooling the upper layers of the planet. The lithosphere becomes thicker the more pronounced this heat pipe process is, but the interior remains warm, as heat is being efficiently removed mainly in the upper layers of the planet, while the deep interior is blanketed by the thick lithosphere. This heat transport mechanism through heat pipes is most significant during the early evolution of terrestrial planets, when large amounts of melt are produced in the interior (Moore et al. 2017; Spohn 1991), but it may still be active today on planets and moons dominated by volcanic activity, such as Jupiter's moon Io (Moore et al. 2017) and perhaps young and strongly tidally heated exoplanets.

Heat Transfer, Planetary, Fig. 2 Qualitative phase diagram for convection of a fluid with viscoelastic rheology including strongly temperature-dependent viscosity. The figure is based on numerical calculations by K. Stemmer and colleagues. It qualitatively shows how the stability fields of the stagnant lid and mobile lid modes of

convection depend on the Rayleigh number, the viscosity contrast across the fluid, and the yield strength for the transition from elastic to plastic deformation. There is a transitional regime termed episodic in which a stagnant lid episodically becomes mobile (Courtesy of K. Stemmer)

Heavy Atom Beams

Raffaele Saladino
Department of Ecological and Biological Sciences, University of Tuscia, Viterbo, Italy

Synonyms

Ion beams; High-energy particles

Definition

Heavy ion beams are accelerated high-energy particles heavier than electrons. The generation of heavy atom beams is a relevant challenge for many fundamental and technological applications, including biomedical therapy and astrobiology studies Dalui et al. (2017). The conventional techniques for the generation of heavy atom beams involve an ion source, the accelerating apparatus and a collision cell for the electron detachment or electron capture processes Rajeev et al. (2013). This apparatus can be configured in a very different technological way. Heavy atom

beams fueled astrochemical transformations in the synthesis of complex organic molecules (COMs) are reported under gas and solid-state conditions Caselli and Ceccarelli (2012) covering space, interstellar and planetary like environments Congiu et al. (2020). They are also responsible for the degradation of organic compounds Smith (2011), thus the balance between the rates for the reactions that contribute to formation and destruction of molecules is of pivotal importance for molecular evolution Ehrenfreund et al. (2002). High-energy heavy atom beams simulating cosmic radiation Ferrari and Szuszkiewicz (2009) have been reported as energy source for the prebiotic synthesis of molecules of biological relevance such as nucleobases, amino acids, and sugars Saladino et al. (2016), and the role played by mineral surfaces in the control of regioselectivity and stereoselectivity of the process deeply investigated in the case of nucleotide synthesis Saladino et al. (2017). In addition, the interaction between heavy atom beams and matter can generate a cascade of low-energy electrons and ions fueling non-selective chemistry for the synthesis of multiple reaction products which favor complexity and variety in the construction of chemical structural motifs Arumainayagam et al. (2019).

Heavy Charged Particle

► [HZE Particle](#)

Heavy Element

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

In the astrophysical context, a heavy element is any element heavier than helium. The term “metal” is also used by astronomers. The definition stems from the fact that only helium and hydrogen (and small quantities of lithium and beryllium) were produced in the few first minutes after the big bang: all other elements were produced afterward, through stellar processing (nuclear reactions or supernovae).

6 Hebe

Hervé Cottin
Univ Paris Est Creteil and Université Paris Cité,
CNRS, LISA, F-94010, Créteil, France

Synonyms

[1847 JB](#)

Definition

6 Hebe is a large S-type asteroid orbiting in the main belt, at about 2.426 AU from the Sun (semimajor axis). Its size is $205 \times 185 \times 170$ km with a mass of about $1.2 \cdot 10^{19}$ kg, making it the 26th largest asteroid of the main belt and 16th in mass. Its orbit has an inclination of 14.751° and an eccentricity of 0.202. This asteroid has drawn specific interest because its proximity to orbital resonances results in a relatively large chance for any 6 Hebe's ejecta to collide with the Earth. Moreover, due to its spectral properties, it has been thought for a long time that 6 Hebe was the source of ordinary H chondrites and IIE iron meteorites. Note that H chondrites are one of the most abundant meteorite family found on Earth: ~34% of falls.

However, the possibility that so many meteorites on Earth could originate from the same asteroid has been weakened by observations of new asteroids with the same spectral properties. Moreover, a detailed surface study of 6 Hebe has concluded that only one-fifth of nearby asteroids with H chondrite type composition could have been produced by 6 Hebe from impacts.

History

Hebe is the sixth asteroid observed. Karl Ludwig Hencke discovered it in 1847.

Copernicus · Epicycles · Eccentric · Equant

Definition

A cosmological worldview where the Sun is located at the center of the Universe.

History

Aristarchus (310–230 B.C.) was the first person to suggest that the Sun, not the Earth, is the center of the Universe. From his measurement that the Sun is 20 times farther away from the Earth than the Moon is, he estimated that the Sun is 7 times larger than the Earth. He argued that it was unreasonable to assume that a larger body (the Sun) should revolve around a smaller body (the Earth).

The heliocentric model was further developed by Nicolaus Copernicus (1473–1543). Copernicus considered the concept of equant in Ptolemy’s model as violating the spirit of uniform circular motion and proceeded to seek an alternative without the use of the equant. Copernicus places the Sun near the center of the Universe, with the Earth and the other five planets revolving around it. The only object that revolves around the Earth is the Moon.

Overview

In 1543, Copernicus published his heliocentric model in the book *Six Books on the Revolutions of the Heavenly Spheres*. In Copernicus’ model, the Earth revolves around a point that is offset (eccentric) from the Sun (Fig. 1). A planet revolves around an epicycle whose center (*E*) revolves around a point which is eccentric from the center of the Earth’s orbit. By employing both eccentric and epicycles, Copernicus was able to simulate the noncircular and nonuniform movement of a planet. Although the Sun is stationary in Copernicus’s model, it is strictly speaking not a Sun-centered (heliocentric) model as the Earth and planets do not revolve around the Sun.

Although Copernicus’s model was not more accurate and had more epicycles than the model of Ptolemy, he did remove some unexpected coincidences in Ptolemy’s model such as the alignment between the lines connecting the planets to the centers of their epicycles being always in parallel with the line connecting the Earth and the Sun, and the planets revolving around the centers of their epicycles at the same rate as the Sun revolves around the Earth. Copernicus’s model also has the aesthetic advantage of providing a natural explanation for the retrograde motions of the planets. From the observed synodic periods (time from conjunction to conjunction or from opposition to opposition) of the planets, he was able to derive the true periods of revolution (sidereal periods) of the planets. The heliocentric model also naturally explains why the planets Mars, Jupiter, and Saturn are brightest during

Heliocentric Worldview, Fig. 1 Copernicus' model of planetary motion. The center of the Earth's orbit (in blue) is offset from the Sun (not shown). A planet (*P*) revolves around in an epicycle (in green) whose center (*E*) revolves

around (in red) a point which is eccentric from the center of Earth's orbit. The final trajectory of the planet is shown by the dashed line (in purple)

opposition, without assuming artificial periods for their epicycles. Most significantly, Copernicus can derive the relative distances between the planets and the Sun, therefore resolving the ambiguity in the order of Mercury and Venus in Ptolemy's model.

The heliocentric distances and sidereal periods of the planets were later used by Johannes Kepler (1571–1630) to formulate his third law of planetary motion. Using the observational data of Tycho Brahe (1546–1601), Kepler showed that planetary orbits have the shape of an ellipse,

with the Sun located at one of the foci of the ellipse. Kepler also suggested that planetary motions are physically driven by the Sun, therefore providing a truly heliocentric model.

Copernicus replaced the hypothesis of rotation of celestial sphere by the hypothesis of a rotating Earth and the apparent annual motion of the Sun by the Earth revolving around the Sun. Copernicus's theory was not immediately accepted because of the lack of observational evidence for a moving Earth and the theoretical objection of our inability to feel such motions.

Empirical evidence for the rotation of the Earth was later found through the detection of the eastward deflection of falling objects in 1831, the rotation of the plane of oscillation of the Foucault pendulum in 1851, and the measurement of the oblateness of the Earth in the twentieth century. Evidence for the Earth's revolution around the Sun was found by the detection of aberration of starlight in 1729, the measurement of stellar parallax in 1838, and the periodic Doppler shift of stellar lines in 1872. Our inability to feel the movement of the Earth was explained by Newton's theory of gravitation, laws of motion, and introduction of the concept of inertial forces.

In the heliocentric model, the sphere of stars no longer rotates around the Earth and there is no need for stars to lie on the surface of celestial sphere. This casted a doubt on the religious doctrine of Heaven being located beyond the celestial sphere. The demotion of the Earth to one of the six planets represented the first step towards the loss of special status of humanity in the Universe.

The Herschel Space Observatory was a ► [European Space Agency](#) (ESA) facility for far-infrared and submillimeter astronomy, providing unprecedented observing capabilities in the ~55–670 μm spectral range. NASA collaborated through the provision of detector technologies and science operations support. With its 3.5 m diameter primary mirror and three science instruments,

Herschel was launched on 14 May 2009 and performed its final science observation on 29 April 2013 once its liquid helium coolant had been exhausted, having carried out ~23,500 h of successful science observing. All data and associated data products are publicly available to the worldwide astronomy community through the Herschel Science Archive. The main science objectives addressed by the mission were ► [interstellar medium](#) physics, star formation and evolved ► [stars](#), and galaxy evolution.

History

Herschel has a long history. Conceived of as the Far Infrared and Sub-millimetre Telescope (FIRST) and proposed to ESA in November 1982 in response to a call for mission proposals issued in July 1982, it was incorporated into the ESA “Horizon 2000” long-term plan in 1984. Over the years, it was the subject of multiple studies adopting a variety of mission designs, spacecraft configurations, telescopes, and science payloads. In November 1993, the ESA Science Programme Committee (SPC) decided that FIRST would be implemented as the fourth “Cornerstone” (CS4) mission. The science payload was selected in 1997–1999, the major industrial contractors in 2000–2001, and in April 2001, the corresponding industrial activities commenced. Meanwhile, in December 2000, FIRST was renamed “Herschel” in recognition of the 200th anniversary of the discovery of infrared light by German-born British astronomer and composer, William Herschel (1738–1822).

The three science instruments, HIFI, PACS, and SPIRE, were delivered and integrated in 2007; final integration, testing, and verification activities took place in ESA’s ESTEC Test Centre from January 2008 to January 2009, after which the Herschel spacecraft was flown to Europe’s spaceport, the Guiana Space Centre in Kourou, French Guiana, for the launch campaign. Herschel was launched together with Planck on an Ariane 5 ECA on 14 May 2009, operated from a large halo orbit around the second Lagrange point (L2) in the Sun–Earth system, and performed its

final science observation on 29 April 2013, when it ran out of superfluid liquid helium coolant. The spacecraft was put into a heliocentric “disposal orbit,” where it will remain indefinitely, and finally turned off on 17 June 2013.

Herschel observers and science data users were supported in the exploitation of Herschel data throughout the post-operation phase, which formally ended in December 2017, but continued at a low level into 2019. The total mission cost is estimated at €1200 million.

Overview

Mission

The Herschel Space Observatory was the fourth “Cornerstone” mission in the European Space Agency (ESA) “Horizon 2000” science plan. Herschel was a facility for far-infrared and submillimeter astronomy, providing unprecedented observing capabilities in the $\sim 55\text{--}670\ \mu\text{m}$ spectral range. With a 3.5 m diameter silicon carbide primary mirror, it offered a much larger telescope and extended longer-wavelength spectral coverage compared to earlier infrared missions such as the Infrared Astronomical Satellite (IRAS), the Infrared Space Observatory (ISO), Akari, and Spitzer. Additionally, it bridged the wavelength gap to ground-based submillimeter facilities, and its data still provide a key observational database for follow-up observations, in particular with the Atacama Large Millimeter/sub-millimeter Array (ALMA).

Herschel was launched together with ESA’s Planck cosmic microwave background mission at 13:12:02UTC on 14 May 2009 by Ariane 5 ECA VA-188 from Europe’s spaceport, the Guiana Space Centre, in Kourou, French Guiana. It operated in a large quasi-halo orbit around the second Lagrange point (L2) in the Sun-Earth/Moon system, with a daily ground contact period of normally about 3 h. Herschel successfully carried out its observing programs until it ran out of superfluid helium coolant on 29 April 2013, putting a permanent end to any further taking of science data. The spacecraft was put into a heliocentric “disposal orbit” and finally turned off on 17 June 2013.

Spacecraft and Telescope

The Herschel spacecraft (Fig. 1) provided the appropriate working environment for the science instruments receiving photons from the telescope, pointed the telescope with required accuracy, autonomously executed the observing timeline, and performed onboard data handling and communication with the ground. The design is modular, consisting of the “payload module” (PLM) supporting the telescope, the “service module” (SVM), and the sunshade/sunshield. The mission lifetime was determined by the exhaustion of the superfluid helium used to cool the scientific instruments in their cryostat: it was designed to meet a requirement of 3.5 years and in fact lasted just under 4 years.

The PLM is dominated by a cryostat vacuum vessel containing a suspended superfluid liquid helium (SLHe) tank, an optical bench with the three scientific instrument focal plane units (FPU) supported on top of the tank, all surrounded by three vapor-cooled shields to minimize parasitic heat loads. The tank contained $\sim 335\ \text{kg}$ or 2320 l of SLHe at launch and a phase separator allowed a continuous evaporation of the liquid into cold gas, keeping the FPUs and their detectors at their required operating temperatures.

The primary mirror of the telescope is 3.5 m in diameter and made of 12 individual petal of silicon carbide brazed into a single unit. It was passively radiatively cooled and had an inflight operating temperature of about 88 K and very low emissivity. The total wavefront error (WFE) of the telescope was less than $5\ \mu\text{m}$ at the focal surface interfacing to the instruments.

The SVM houses “warm” payload electronics on four of its eight panels and provides the necessary infrastructure for the satellite such as power, altitude and orbit control, the onboard data handling and command execution, communications, and safety monitoring. It also provided a thermally controlled environment, which was critical for some of the instrument units. Finally, the SVM also provides mechanical support for the PLM, the sunshield/sunshade, and a thermal shield to thermally decouple the PLM from the SVM. It also supported the main mechanical load path during launch.

instrument focal plane units on the optical bench on top of the helium tank. Also illustrated is the “Russian doll” structure minimizing “parasitic” heat loads (ESA)

Science Instruments

Herschel has three science instruments provided by European member states and the scientific community, with NASA supplying detector technologies for two of them. The main characteristics of the Photodetector Array Camera and Spectrometer (PACS), the Spectral and Photometric Imaging REceiver (SPIRE), and the Heterodyne Instrument for the Far Infrared (HIFI) are shown in Table 1.

Basic Methodology

Operations and Science Ground Segment

Mission operations were provided by the Mission Operations Centre (MOC) at ESA’s European Space Operations Centre (ESOC) in Darmstadt, while the science operations were conducted at five centers:

Herschel Mission, Table 1 Herschel science instrument main characteristics

Acronym	Instrument	Principal investigator
PACS	Imaging camera and grating spectrometer, spectral coverage ~55–205 μm	A. Poglitsch, MPE, Garching (DE)
SPIRE	Imaging camera and FTS spectrometer, spectral coverage 194–671 μm	M. Griffin, U. Cardiff (UK)
HIFI	Heterodyne spectrometer, spectral coverage 157–212 and 240–625 μm	F. Helmich, SRON, Groningen (NL)

- The Herschel Science Centre (HSC) at the European Space Astronomy Centre (ESAC), near Madrid, provided by ESA

- Three dedicated Instrument Control Centres (ICCs), one for each instrument, provided by the respective PIs
- The NASA Herschel Science Center (NHSC), at JPL in Pasadena, provided by ► [NASA](#)

Mission operations ended after the observatory was passivated in 2013, while science operations led by the HSC, supported by the ICCs and the NHSC (primarily for the US science community), continued until the end of 2017, supporting the community in exploiting the science data throughout the post-operation phase. Data processing software and science archive were improved during this time, refined products ingested into the archive, and documentation enhanced, finally yielding the Herschel Legacy Archive.

Observing

Herschel was operated as an observatory, with roughly a third of the observing time guaranteed to the three instrument teams and the rest available as open time to the worldwide community. Astronomers made competitive applications for the open time on Herschel competitively by responding to calls for proposals (Announcements of Opportunity – AOs), providing the science objectives and the definition of the actual observations being proposed. There were two open AOs issued after the mission had been launched, resulting in roughly 600 proposals each time. All proposals were reviewed by the independent Herschel Observing Time Allocation Committee (HOTAC), and just over half were accepted at each AO. The observations by the successful proposers were then carried out. A small amount of the open time was allocated as discretionary time.

Given that Herschel would not have the benefit of a pre-existing all-sky survey for much of its wavelength coverage, it was decided early on that large so-called key programs (KPs) in the form of “large spatial and spectral surveys” would be selected pre-launch and executed early in the mission. A dedicated AO for KPs was issued prior to flight and roughly 48% of the total observing time was allocated to them – the majority of Herschel’s highly cited papers result from KP data.

Herschel successfully observed until it ran out of superfluid helium coolant in April 2013. Since 29 October 2013, all Herschel science observations have been publicly available from the Herschel Science Archive (HSA) to the worldwide astronomical community. The HSA offers over 37,000 successful observations obtained in ~23,500 h of science observing (exceeding the nominal mission by ~20%), covering almost 10% of the sky. In addition, there are over 6,600 science calibration observations publicly available from the archive.

Key Research Findings

The “Cool Universe”

Herschel’s broad remit was to study the low-temperature or “cool universe.” It was the first and to date only space facility dedicated to the far-infrared and sub-millimeter regions of the electromagnetic spectrum. Roughly half the energy emitted in the universe since the formation of the cosmic microwave background (CMB) has been absorbed by dust in the ► [interstellar medium](#) (ISM) in our ► [Milky Way](#) and other galaxies, and subsequently reemitted lower temperatures and thus at the longer Herschel wavelengths. The integrated spectrum of the reradiated emission peaks in the 100–200 μm range. In addition to the dust continuum, gas in the ISM emits in a profusion of spectral lines that lie in the Herschel wavelength range.

The main scientific focus of Herschel was the formation and evolution of stars and galaxies, and the physics and chemistry within the ISM from which they form and interact with. This spanned our own Milky Way and extragalactic space beyond. In addition, Herschel studied disks of gas and dust around young stars providing information and comparisons with the global properties of extrasolar planetary systems around nearby stars, and also observed a range of objects in our own solar system, including planets, moons, comets, and asteroids.

In October 2013, shortly after the end of the mission, a symposium titled “The Universe Explored by Herschel” symposium was held,

with ~360 participants making in excess of 100 oral and ~200 poster presentations. Several other symposia dedicated to Herschel science topics have since been held.

Since the end of mission, papers based on Herschel data have continued to be published at a steady rate of 200–300 a year, illustrating the continued importance of its far-infrared and sub-millimeter observations: at the time of writing (August 2021), approximately 3,000 papers have been published in total. It is impossible to give a full overview here – rather, a few illustrative highlights are briefly described below. See the references for links to more complete information.

The Galactic Plane

One of the largest legacy data sets generated by Herschel is its complete 360° photometric survey of the entire galactic plane in five bands from 70 to 500 μm . Figure 2 shows a small fraction of the Herschel survey data centered at galactic longitude $l = -10^\circ$, combined with shorter wavelength data from NASA's Spitzer mission – dramatic structure is clearly visible on all scales. Together with ancillary data at other wavelengths including those of Spitzer, these data enable astronomers to address a number of fundamental questions regarding the global workings of our Galaxy, in particular with respect to (high-mass) star formation and the resulting feedback on the ISM environment. The aim of such studies is to derive

global star formation rates, in order to construct a new 3D model of the Milky Way and to map the essential critical parameters including column density thresholds, and the rate and efficiency of star formation in our galaxy.

A Stellar Nursery

Figure 3 shows a combined Herschel and Planck view of a stellar nursery in the Aquila Rift at a distance of approximately 260 parsecs. Far-infrared (250, 350, and 500 μm) data from Herschel SPIRE reveal the low-temperature dust cloud comprising many filaments, in which some 700 clumps of gas and dust are found. Approximately 100 of these are thought to be protostars in the final stages of collapse into stars. Analysis of these and other Herschel SPIRE and PACS data in other regions led astronomers to propose that filaments play a key role in the collapse of clouds to star-forming clumps, individual stars, and clusters such as Westerhout 40 seen at left. Overlaid on the Herschel data are “streamlines” illustrating the magnetic field orientation as derived from Planck data – the interplay between gravity, radiation, and magnetic fields lies at the core of the star formation process.

Astrochemistry Revealed

In addition to its long-wavelength photometric imaging capabilities, Herschel was also able to undertake high-sensitivity, high spectral

H

Herschel Mission, Fig. 2 ESA Herschel and NASA Spitzer view of approximately 3% of the Galactic Plane. Combining Spitzer/MIPS 24 μm (blue), Herschel/PACS 160 μm (green), and Herschel/SPIRE 250 μm (red) data, it covers 12° in galactic longitude centered at $l = -10^\circ$ and

stretches $\sim 1.5^\circ$ above and below the plane. Observations from the Herschel Hi-GAL Key Programme (PI: S. Molinari) and the Spitzer MIPS/GAL Program (PI: S. Carey). (Image processing by H. Bouy (CAB CSIC), E. Bertin (IAP), and B. Merin (ESA))

Herschel Mission,

Fig. 3 The Aquila Rift star-forming region as seen by Herschel and Planck. The underlying image is an RGB combination of Herschel SPIRE data at 500, 350, and 250 μm , respectively, and the overlaid “streamlines” illustrate the direction of the magnetic field, as derived from Planck data. (ESA/Herschel/Planck, J. D. Soler, MPIA)

resolution surveys of the many emission lines in its wavelength range coming from cool gas in the ISM, enabling comprehensive studies of astrochemistry.

Figure 4 shows part of a HIFI spectral scan made towards the Orion Nebula, one of the nearest regions of massive star formation: among the molecules identified in this spectrum are water, carbon monoxide, formaldehyde, methanol, dimethyl ether, hydrogen cyanide, sulfur oxide, sulfur dioxide, and their ► [isotope](#) analogues.

This spectrum demonstrates the spectral richness of regions of star and planet formation; the complete survey has more than 20,000 lines, enabling a much deeper understanding of the astrochemistry of the region. Similar broad spectral surveys were conducted in many regions throughout the Milky Way.

Water

A particular focus of Herschel spectroscopy was the study of water in gas form throughout the universe. For example, one key program (WISH) was dedicated to tracing water through the various

stages of star and planet formation, enabling a detailed analysis of the physical and chemical conditions and processes. A comprehensive review of the WISH results, along with other Herschel observations of water, was published by van Dishoeck et al. (2021)

Closer to home, a combined PACS and HIFI spectroscopic study of Jupiter found direct proof that the bulk of the water currently present in the planet’s stratosphere was delivered by Comet Shoemaker-Levy 9, the many fragments of which struck the planet in 1994. The PACS observations in a grid of 25 points across the disk of Jupiter showed that the water is predominantly confined to the southern hemisphere, where the comet struck. The HIFI observations indicate that the bulk of water is confined to pressures lower than 2 millibars, corresponding to high stratospheric altitudes – well above the uppermost part of the troposphere which effectively acts as a “cold trap.” As a consequence, the water in the stratosphere is inferred to have been delivered from an external source, identified as the 1994 comet fragment impacts (Fig. 5).

H

Herschel Mission, Fig. 4 A part of a Herschel/HIFI spectral scan (white curve) of the Orion Nebula, covering a frequency range of approximately 1.06–1.15 THz,

overlaid on a Spitzer Space Telescope mid-infrared image of the region. (ESA/HIFI/HEXOS/E. Bergin)

Herschel Mission, Fig. 5 The distribution of water in the stratosphere of Jupiter. White and cyan indicate highest concentration of water, while blue indicates smaller amounts. The map has been superimposed over an image of Jupiter taken at visible wavelengths with the Hubble Space Telescope. (ESA/Herschel/T. Cavalié et al.; Jupiter image: NASA/ESA/R. Beebe (New Mexico State University))

The Evolution of Galaxies

In addition to its wide-ranging studies of the Milky Way, Herschel also dedicated a significant fraction of its observing time to galaxies across the universe, in both pointed observations of individual galaxies and deep and/or wide-field surveys of populations of galaxies spanning a wide range in redshift.

Many of these surveys were conducted in well-known “deep field” locations including the Lockman Hole, the Chandra Deep Field North, the two GOODS field, and the COSMOS field (see Fig. 6), and more, regions that have been well-studied by telescopes covering much of the electromagnetic spectrum. Together, these surveys enabled important studies of the evolution of star formation, cosmic recycling, feedback, and the role of black holes across cosmic time.

Herschel Mission, Fig. 6 This image shows the COSMOS field as seen at far-infrared and submillimeter wavelengths with the Herschel SPIRE instrument. The COSMOS field is a two-square degree patch of the sky that is being extensively observed across the electromagnetic spectrum to study star formation in distant galaxies. The image contains thousands of galaxies; each dot in the image is a galaxy. (ESA/Herschel/SPIRE/HerMES Key Programme)

Herschel, William

Fernando B. Figueiredo
CITEUC, University of Coimbra, Coimbra,
Portugal

History

William Herschel (1738–1822) was a German-born musician and, most famously, astronomer, who spent most of his life in Britain. He discovered Uranus in 1781, thereby doubling the size of the known solar system. Other important astronomical discoveries concerned the atmosphere of Venus and others planets of the Solar system: between 1787 and 1789 he discovered Mimas and Enceladus, Saturn’s sixth and seventh satellites, and in 1787, he identified the first two satellites of Uranus, Oberon and Titania. With the assistance of his sister Caroline Herschel (1750–1848), an important astronomer by herself, whose most significant contribution to astronomy was the discovery of several comets, he worked on a catalog of nebulae and star clusters (the observational reductions were primarily made by Caroline). As an astrobiologist, it is interesting to note that Herschel believed it likely that the Moon and planets harbored life.

William Herschel had only one child, John Frederick William Herschel (1792–1871), also an astronomer who made important contributions to stellar astronomy (namely star clusters and nebulae).

The European Space Agency's Herschel Space Observatory that was launched on May 14, 2009, was conceived to study the darkest and coldest parts of the Universe by the light of the far-infrared and submillimeter portions of the spectrum.

Color-magnitude diagram; HR diagram; Luminosity-temperature diagram

Acronyms

HRD

Definition

The Hertzsprung-Russell diagram plots the ► [magnitude](#) and color of stars, which are

converted via theoretical models and distances into stellar luminosities and surface ("effective") temperatures. Comparison with theoretical tracks, the "paths" in the diagram corresponding to changes in observed properties as the star evolves, then allows the determination of the mass or age of a star or cluster. Note in the following the astrophysical use of the term "burning" to signify nuclear fusion (e.g., of hydrogen to helium).

Since the beginning of the twentieth century, astronomers have been using the "Hertzsprung-Russell diagram" (from the name of its discoverers, in the early twentieth century; hereafter HRD) to classify stars and understand their evolution, from their formation to their very late stages.

Overview

When plotted in the HRD, the stars do not appear randomly distributed (see Fig. 1). There are some regions that are more populated and others that are almost empty. There is an evident relation between the density of a region and the duration of the ► [stellar evolution](#) phase that occurs in that region. During their evolution, stars pass from long-lasting hydrostatic burning (nuclear fusion) phases to quick structural readjustments. While it is easy to observe the stars in regions where the hydrostatic burnings occur, very few stars can be observed during their readjustment phases.

Basic Methodology

Observationally, astronomers first determine the magnitude and ► [spectral type](#) of the stars. These numbers are then transformed into luminosity and temperature, which are physical quantities that can be compared with models. This assumes the capability (1) to know the distance (to convert magnitudes into luminosities), which is determined by various methods (to an accuracy of ~20–30% in the case of young stars), and (2) to convert from spectral types to temperatures,

Hertzsprung-Russell Diagram, Fig. 1 Hertzsprung-Russell diagram (Courtesy Javier García Nombela, art-res.net). The observational units are in yellow (absolute magnitude versus spectral class) and the theoretical ones in white (luminosity versus effective temperature). Some

significant regions are indicated in gray. The duration of the main sequence for the different masses is indicated in red. Lines of isoradius are sketched in green. The names of some known stars are indicated

which can be done with models of stellar photospheres. For “simple” stars like the Sun, the temperature determination is very precise (<1%), but for more complex spectra, like the T Tauri stars which have a circumstellar disk, the uncertainty may reach 10–20% or more.

Key Research Findings

Populated Regions

When the HRD is used with a sample of observed stars, it gives statistical information about the surface characteristics of stars, defining specific

regions. Each region can be associated to a particular evolutionary phase by the knowledge of stellar evolution and theoretical tracks (see below). There are many interesting regions standing out in the diagram. Among them, one can mention the following ones.

Main Sequence

The great majority of the stars lie in the diagonal, the main sequence (MS), which represents the zone where stars convert hydrogen into helium, i.e., the first and longest phase of the nuclear life of stars. This phase can last billions of years for a star like the Sun. Since stars follow a

mass-luminosity relation, with $L \propto M^3$ during the MS, the location of a star on the MS allows an estimation of its mass. After this phase, the fusion of hydrogen goes on in a shell, while the core contracts and the envelope expands: the stars cross rapidly the HRD and become red giants or supergiants.

Giants and Supergiants

The giants and supergiants regions mark the location of the HRD where hydrostatic helium burning occurs.

Stars between 0.8 and $2 M_{\odot}$ (solar masses) leave the MS to climb on the red giant branch until they undergo a flash which ignites helium fusion in their core. After the flash, they settle on the horizontal branch (giants region) where they burn helium quietly. Between 2 and $10 M_{\odot}$, the core helium burning starts smoothly, following the same path in the HRD. Above $10 M_{\odot}$, most of the central helium burning occurs in the red supergiants region.

After central helium exhaustion, stars between 2 and $10 M_{\odot}$ populate the asymptotic giant branch, where an unstable double shell burning (a shell of helium burning and another of hydrogen burning) drives thermal pulsations.

Instability Strip

The instability strip marks a region in the HRD where stars become unstable to radial pulsations. This region is occupied by stars of different types, among which two are commonly used as distance calibrators:

1. RR Lyrae, which are old giants of low **metallicity** on the horizontal branch.
2. Classical Cepheids, which are helium burning stars between 4 and $12 M_{\odot}$.

The distance calibration is based on the attenuation from the absolute magnitude (which represents the intrinsic stellar luminosity) to the apparent magnitude (reflecting the observed brightness; Hertzsprung 1913). While in the normal case, it is extremely difficult to determine the absolute magnitude of a star, RR Lyrae and Cepheids present, respectively, a metallicity-

luminosity and a period-luminosity relation that have long been thought to offer an easy knowledge of their absolute magnitude, since the periods and metallicities can be measured. It is now known that those relations are more complex and less direct than previously considered (see Sandage and Tammann 2006, and references therein), and their use as distance calibrators must be considered with caution.

White Dwarf Location

At the end of the evolution, stars below $\sim 10 M_{\odot}$ expel their envelope as a *planetary nebula* and settle on the white dwarf branch, where they progressively cool.

Theoretical Tracks

When theoretical tracks are plotted in the HRD, they offer an evolutionary link between the different populations by giving the time sequence of the surface characteristics by which the stars pass throughout their evolution.

An example of a theoretical HRD is given in Fig. 2 (Schaller et al. 1992). It plots the evolution of the stars from the central hydrogen ignition to the end of helium burning. For low- and intermediate-mass stars, that is the end of the evolution, while for massive stars (above $10 M_{\odot}$), the nucleosynthetic activity continues in the core, up to silicon burning. However, after helium exhaustion, the evolution of massive stars accelerates significantly so the core and the envelope decouple: their external properties remain almost identical throughout the advanced phases up to the time of the supernova explosion.

Before the Main Sequence: Hayashi Tracks

From the main sequence onwards, the energy output is always *thermonuclear* in origin, with successive nuclear reaction networks driving important changes in the overall stellar structure.

Before the main sequence, however, the situation is entirely different, since the stars slowly shrink as the radiation generated by gravitational contraction is evacuated in the form of light. In other words, the energy of “pre-main sequence” stars (protostars and T Tauri stars) is *not* nuclear in origin but is drawn only from *gravitation*. This

Hertzsprung-Russell Diagram,

Fig. 2 Theoretical tracks of stellar evolution in the Hertzsprung-Russell diagram (From Schaller et al. 1992), showing luminosity (relative to the Sun) (scale on the left) and bolometric magnitude (M_{bol} , scale of the right) versus effective temperature. The shaded area represents the regions of H and He burning. Stellar mass indicated along the main sequence line

“simplification” explains that, as early as 1966 (when only low-power computers were available!), theoretical models of pre-main sequence evolution could be devised by Hayashi and his collaborators in Japan.

This early work on “Hayashi” evolutionary tracks in the HRD distinguished two main phases which are still used as a reference today:

1. The “convective” phase, in which the stars are fully convective and evolve essentially isothermally (i.e., at the same temperature, so that the theoretical HRD tracks as a function of mass are all vertical).

2. The “radiative” phase, in which a radiative core develops inside the star, which then becomes hotter but evolves at an almost constant luminosity (following the contraction in radius).

Figure 3 illustrates pre-main sequence evolutionary tracks, running through observational points for the young Orion nebula cluster: each point represents a star, ordered by luminosity and temperature. For a star like the Sun, the convective phase lasts about 10 million years, during which the temperature is held almost constant, around 4600 K, and the luminosity drops by a

Hertzsprung-Russell Diagram, Fig. 3 Hertzsprung-Russell diagram of 934 low-mass members of the young Orion Nebula Cluster (Hillenbrand 1997) and theoretical pre-main sequence tracks, labeled in masses and ages (dotted lines). The spectral types corresponding to surface

temperatures (T_{eff}) are also indicated. Most stars appear to be younger than a few million years, with masses from $0.1 M_{\odot}$ or less, up to a few $M_{\odot}$ (higher masses are located outside of this diagram). (From Montmerle et al. 2006)

factor of ~ 20 with respect to the early T Tauri stage (when the young Sun starts to be optically visible). Then the radiative phase lasts from ~ 10 million to ~ 100 million years at a roughly constant luminosity ($\sim 1 L_{\odot}$), until the thermonuclear reactions transforming hydrogen into helium start. This marks the beginning of the main sequence, already described, on which the Sun has been for ~ 4.5 billion years and still is today.

Applications

Once located in the HRD, observed stars can be compared to theoretical tracks. From such a confrontation, one can evaluate the mass and evolutionary status of the star.

The HRD can also be used to plot a whole cluster (see Fig. 3 for a young cluster and Fig. 4 for an evolved cluster). The graph obtained will be then compared to theoretical **isochrones** (location of stars with different masses at a given age), so the age of the cluster can be determined.

The comparison between observed stars and theoretical tracks is neither straightforward nor simple. As mentioned above, the comparison between observation and theory implies a conversion from observational units (color and magnitude) to theoretical ones (effective temperature and luminosity), with some uncertainties in the conversion. Some observed stars may be unresolved binaries, giving access only to the addition of their magnitude and to the mean of their color index. Some stellar parameters (as the

Hertzsprung-Russell Diagram, Fig. 4 Color-magnitude diagram of several galactic clusters (From Sandage 1958). The age of the turn-off from the main sequence is indicated on the *right* axis. Historically, this is the first compilation of this type. The shortest ages (less than a few 10 million years) are wrong, because the “pre-main sequence” evolutionary phases were not known at the time

chemical composition or the rotation rate, e.g.) can modify the location in the HRD of the theoretical tracks. A good knowledge of the observed object and an adequate choice of the stellar models are needed to get valuable information from such a comparison. Note that some physical inputs in the models are still uncertain (treatment of convection, mass loss prescription, magnetic fields) and can alter the tracks.

Future Directions

The stellar evolutionary tracks are established for a fixed mass sufficiently precisely that one can have an estimate of the mass and age of a star. But a major phenomenon still defies modelers. This is mass loss and its interplay with evolution, for which only crude theories exist. In the case of T Tauri stars, especially in the early stages, accretion (from a circumstellar disk) is important but is

taken only phenomenologically into account in the evolutionary models.

Heterocycle

Shin Miyakawa¹ and Kensei Kobayashi²

¹Tokyo Institute of Technology, Yokohama, Japan

²Department of Chemistry, Yokohama National University, Yokohama, Japan

Definition

A heterocycle is an organic compound that contains within a ring structure, which can be aliphatic or aromatic, at least one element other than carbon, such as nitrogen, oxygen, or sulfur. Examples are purines, pyrimidines, imidazoles, and quinolines. The nitrogen heterocyclic ring system imidazole occurs in histidine (one of the 20 coded protein amino acids), and some purines and pyrimidines which occur in DNA and RNA as nucleic acid bases.

These structures have been detected in carbonaceous chondrites (e.g., purines, pyrimidines, and hydantoin). Ethylene oxide, an O-containing heterocycle compound, has been identified in the interstellar medium. In prebiotic experiments, these compounds can be formed by electric discharges and proton irradiation of gas mixtures containing carbon, nitrogen, oxygen, and hydrogen, such as CH_4 - N_2 - H_2 - O_2 . Heterocycles including purines and pyrimidines have been detected in carbonaceous chondrites.

Heterotrophic Hypothesis

Robert Pascal

Institut des Biomolécules Max Mousseron CC1706, Université de Montpellier II, Montpellier, France

Synonyms

[Prebiotic soup hypothesis](#)

Definition

According to the heterotrophic hypothesis for the origin of life, early organisms depended on abiotically synthesized organic molecules for their structural components and as an energy source. The hypothesis is usually considered in connection with abiotic organic matter of atmospheric origin, but is also consistent with extraterrestrial inputs (► [meteorites](#), micrometeorites, comets) or hydrothermal synthesis. The dilution of organic matter in the ocean is considered sufficient reason to rule out its relevance by many opponents.

History

In 1871, the mention of a “warm little pond” by Darwin may be considered as the first mention of this hypothesis. Subsequently, it was more clearly formulated by Oparin ([1924](#)), Haldane ([1929](#)), and Urey ([1952](#)), ideas which ultimately led to the Miller experiment ([1953](#)).

[1,3,5,7-Tetraazatricyclo\[3.3.1.1^{3,7}\]decane](#); [11,3,5,7-Tetrazaadamantane](#); [Formamine](#); [Hexamethyleneamine](#); [Hexamine](#); [HMT](#); [Methenamine](#); [Urotropine](#)

Definition

An adamantane-like heterocycle ($C_6H_{12}N_4$) formed from the condensation of six ► [formaldehyde](#) and four ► [ammonia](#) molecules.

Overview

Hexamethylenetetramine (HMT) is a condensation product formed readily from gaseous, aqueous, or organic solutions of ammonia and formaldehyde. It was first synthesized and characterized by the Russian chemist Aleksandr Butlerov (who also discovered the ► [formose reaction](#)) in 1859 and was the first organic compound with a solved X-ray crystal structure. HMT

has a molecular formula of $C_6H_{12}N_4$ and is generated in a highly exothermic condensation (-55 kcal/mol) from six formaldehyde and four ammonia molecules with the loss of six waters. The exothermicity results from the transformation of six pi bonds into six sigma bonds. It is a white crystalline powder with a sublimation temperature of 285 – 295 °C and an adamantane-like chemical structure with tetrahedral symmetry. It is soluble in chloroform, ethanol, and water (850 g/L at 25 °C) and insoluble in diethyl ether.

It is commercially produced by passing gaseous ammonia into a concentrated solution of aqueous formaldehyde with subsequent removal of water under reduced pressure. Solid HMT can be more easily obtained on a small scale by passing gaseous ammonia into a solution of paraformaldehyde dissolved in refluxing toluene with concomitant water removal (i.e., a Dean-Stark trap).

HMT is stable in neutral and basic aqueous media, with an equilibrium constant approaching 10^{10} . In acidic media, however, it is hydrolyzed to methanimine (H_2CNH), formaldehyde, and ammonia. Synthetically, HMT is useful in the alkylation of primary amines (Delepine reaction) and in the generation of amino alcohols by reaction with oxiranes.

HMT is produced as the primary product (35% yield after 45 days at rt) from the UV irradiation of methanol-ammonia-water mixtures and has been synthesized in laboratory experiments that approximate conditions in the interstellar medium. The spectral properties of HMT and its photolysis products (namely, the 2160 cm^{-1} absorption) indicate that it may comprise a portion of interstellar ice grains and icy satellites.

High-Mass Star

Nikos Prantzos

Institut d'Astrophysique de Paris, Paris, France

Definition

Stars with an initial mass on the ► [zero age main sequence](#) above $\sim 8 M_{\odot}$ are considered to be high-mass stars. They evolve in a short timescale (< 25 Myr) by nuclear fusion of successively all available nuclear fuels, up to ^{56}Fe . The most massive of them suffer heavy mass losses through stellar winds, revealing their nuclear-processed layers (He rich or C rich). At the end of their life, they have developed an “onion skin” structure, with heavier elements lying toward the center. Gravitational collapse of the Fe core turns into a supernova explosion, ejecting most of the mass in the form of heavy elements. They are the major nucleosynthesis sites in the universe, and they leave behind either a ► [neutron star](#) or a ► [black hole](#).

HII Region

Daniel Rouan

LESIA, Observatoire Paris-Site de Meudon, Meudon, France

Synonyms

[H⁺ region](#)

Definition

An H II region is an astrophysical object belonging to the ► [interstellar medium](#) and consisting in a cloud of hot ► [plasma](#) of protons and electrons at about 10,000 K. The name stems from the old appellation H II for the ionized state of hydrogen (now H⁺), as opposed to the neutral state H I. The plasma is produced by photoionization of the hydrogen in an interstellar cloud caused by the ultraviolet radiation from nearby hot massive stars of ► [spectral type](#) O and B. The stars are generally born in a giant ► [molecular cloud](#) and ionize the gas around them that was not condensed into stars. The occasional recombination of a proton and an electron produces a cascade in the energy levels with emission of photons that explains why H II regions appear as luminous nebulae. Their spectrum contains mainly strong H I recombination lines, especially the H α line responsible for the reddish color, as well as forbidden lines (transitions from metastable states, denoted in astronomy by square brackets) such as those from ionized oxygen and nitrogen ([O III], [O II], [N II]). The plasma is also a source of free-free (bremsstrahlung) emission mainly detected in the radio domain. *Compact* H II *regions* designate the youngest ones. The Orion nebula, easily seen with binoculars, is one archetype of an H II region (Fig. 1).

Cross-References

- [Interstellar Medium](#)

HII Region, Fig. 1 The Orion nebula is the prototype H II region, that is, a cloud of hydrogen in the Galaxy, ionized by hot stars in the vicinity. The *red* color results from the recombination of protons and electrons producing a cascade of energy with emission of light

Hill Radius/Sphere

Sean N. Raymond
Laboratoire d'Astrophysique de Bordeaux,
CNRS, Université de Bordeaux, Bordeaux,
France

Synonyms

[Roche radius](#)

Definition

The region around a planet within which the planet's gravity dominates that of the star it orbits is called the Hill sphere, whose radius is called the Hill radius. The Hill radius is given by $R_{\text{Hill}} = a(m_p/3M_{\text{star}})^{1/3}$, where a is the orbital distance of the planet from the star, m_p is the planet's mass, and M_{star} is the stellar mass. The Earth's Hill radius is roughly 0.01 AU, and Jupiter's is about 0.35 AU. The Hill sphere is the same as the Roche

sphere or Roche lobe, but is not to be confused with the Roche limit.

Hill/Lagrange Stability

Rory Barnes
Astronomy Department, University of
Washington, Seattle, WA, USA

Definition

In planetary dynamics, stability refers to an aspect of the orbital motion that remains constant in time, for example, that all planets remain bound to their star. Hill stability only requires that the ordering of the orbiting bodies remain constant, meaning that the outermost planet may leave the system. The

advantage of considering Hill stability is that it can be analytically treated. In contrast, Lagrange stability requires any and all orbital oscillations to remain bounded for all times. Lagrange stability is, therefore, a type of Hill stability, but can only be assessed via N-body simulations. Many planetary systems appear to lie near these boundaries.

Hipparcos

Michel Viso
Innovaxiom, Paris, CX, France

Definition

In 1981, ESA approved a mission covering, for the Agency, a new astronomical field. Hipparcos (originally an acronym for High Precision Parallax Collecting Satellite) was developed to determine the positions, distances, and proper motions of more than 100,000 stars with an accuracy improved by a factor of 10–100 compared to ground-based observations. In the process, it collected also data on their variability and identified and characterized binary systems.

Hipparcos, a 500 kg spacecraft, was launched into geostationary transfer orbit by an Ariane-4 launcher on 8 August 1989. However, the apogee boost motor did not fire, and it could not reach its planned geostationary orbit. Operations were conducted from a highly elliptical orbit with a period of around 10 h.

Overview

By November 1989, Hipparcos started its operational mission. The observations lasted 3.5 years, ending in August 1993. Processing and verifying the data took another 3 years. The Hipparcos Catalogue, with 118,218 entries, was finalized

on 8 August 1996, surpassing all of the original scientific goals. A larger but less accurate “Tycho Catalogue,” derived from the star mappers of the satellite’s attitude control system and incorporating 1,058,332 star positions, was also compiled. In 1997, the data set was published in 17 volumes. The enlarged Tycho 2 Catalogue of 2.5 million stars was published in 2000.

Hipparcos was the first space mission dedicated to measuring the positions of the stars. Beyond its impact on basic stellar physics and on galactic structure and dynamics, Hipparcos helped to predict the impacts of ► [Comet Shoemaker-Levy 9](#) on ► [Jupiter](#), identified stars that will pass close to the Sun, established the distances of stars possessing planets even though these planets were discovered only after the end of the mission, identified a group of stars that were captured by our Galaxy when it was young, fundamentally improved the cosmic distance scale (making the universe bigger and younger), and confirmed Einstein’s prediction of the effect of gravity on starlight.

A new ESA mission for astrometry, Gaia, was launched using a Soyouz Fregat in December 2013 from Kuru in French Guiana.

David W. Latham¹ and Nader Haghighipour²
¹Harvard-Smithsonian Center for Astrophysics, Cambridge, MA, USA
²Institute for Astronomy, University of Hawaii-Manoa, Honolulu, HI, USA

Synonyms

[High Resolution Echelle Spectrometer](#)

Definition

HIRES (High Resolution Echelle Spectrometer) is a high-resolution spectrograph on the Keck

I telescope in Hawaii. It was originally designed as a general-purpose instrument, but one of its main applications has been the determination of radial-velocity orbits for stars hosting exoplanets in order to derive planetary masses. Because the input is a slit, an iodine gas absorption cell is introduced into the stellar beam in order to calibrate the instrumental profile and wavelength scale of each stellar observation. The data analysis requires also a high-quality template observation of each star without the iodine and a fundamental calibration of the spectrum of the absorption cell at very high spectral resolution. HIRES has achieved a performance approaching velocities as low as 1 m/s. HIRES has contributed to the discovery of several hundred extrasolar planets including the first super-Earth, GJ 876 d, several potentially habitable planets around stars such as GJ 667C and Gliese 581, and the confirmation of Kepler 78b, an Earth-sized planet detected by the Kepler space telescope. HIRES and ► [HARPS](#) on the 3.6-m telescope at the European Southern Observatory on La Silla are now the premier instruments for determining the masses of small planets.

Histidine

Henderson James Cleaves II
 Earth-Life Science Institute (ELSI), Tokyo
 Institute of Technology, Tokyo, Japan
 Blue Marble Space Institute of Science,
 Washington, DC, USA
 Center for Chemical Evolution, Georgia Institute
 of Technology, Atlanta, GA, USA

Definition

Histidine is one of the 20 ribosomally encoded protein ► [amino acids](#). It was first isolated by the German physician and biochemist Albrecht

Kossel in 1896. It is distinguished by having a side chain with an imidazole ring, which has a pK_a of approximately 6. Histidine has an isoelectric point (pI) of 7.6; thus, at typical intracellular pH values, relatively small shifts in pH can greatly change its average charge. When protonated, the imidazole ring is positively charged, with the positive charge distributed between both ring nitrogen atoms, which can be represented by two resonance structures. The imidazole ring of histidine is aromatic at all pH values as it contains six π electrons, is a common coordinating ligand in metalloproteins, and is a part of the catalytic sites of many enzymes.

Histidine has not been identified in carbonaceous chondrites and is difficult to be formed in Miller-type prebiotic synthesis experiments, while imidazole can be easily obtained in them.

Definition

Homochirality refers to a property of a group of molecules composed of chiral units. It is an important structural property of molecules that arises in the study of their stereochemistry, where molecules can have the same molecular formula and

sequence of bonded atoms but different in their three-dimensional spatial structure. An enantiomer is one of two nonsuperimposable mirror molecules that differ in their orientation of a chiral unit, much like your left and right hand differ in their chiral (mirror-image) orientation by the position of your thumb. Indeed, the word ‘chiral’ derives from the Greek word for ‘hand’, and biomolecules displaying a mirror symmetry are either “left-handed” (L) or “right-handed” (D). A macromolecule is homochiral if the constituent molecules share the same enantiomer: that is, if the component molecules all share the same handedness. Homochirality is an important feature of terrestrial biochemistry. All life on Earth is composed of homochiral macromolecules (with rare exceptions); for example, only left-handed (L) amino acids are encoded in proteins, and right-handed (D) sugars form the backbones of DNA and RNA.

Overview

Macromolecular homochirality is a universal feature of life on Earth, and is regarded as a feature that might be distinctive to life (Wu et al. 2012). This ubiquity across all known life makes homochirality a critical area of astrobiological research in both the study of the origin of life and the search for life beyond Earth according to agencies such as NASA (Hays et al. 2015) and the National Academies of Sciences (National Academies of Sciences and Medicine 2019). Major classes of biomolecules are homochiral. All known life almost exclusively uses L-amino acids and D-sugars in its biochemistry, with few exceptions (Caforio et al. 2018; Arkhipova et al. 2019). This preference extends to the macromolecular level where biopolymers are assembled from chiral subunits such that all monomers possess the same chirality: one finds only L-amino acids in proteins and only D-sugars in ► [DNA](#) and ► [RNA](#), with no trace of the “unnatural” D-amino acids and L-sugars in either type of polymer chain (Bonner 1996; Karunakaran et al. 2019), although they may be found in metabolic pathways (Miyamoto et al. 2020). The preference

for only one molecular handedness is essential to the proper folding of known biopolymers and the functioning of most biochemical processes in extant life.

Despite the prominence of homochirality in biochemistry, the origin of biological homochirality is not known and presents one of the longest standing mysteries in studies of the origin of life (Glavin et al. 2020). Laboratory syntheses of amino acids and sugars generally yield racemic mixtures (equal amounts of both the L- and D- enantiomers) under prebiotically relevant conditions (Parker et al. 2011). Therefore, a chiral selection process was required at some stage in the origin or early evolution of life on Earth.

Various theories have been proposed to explain how homochirality might have first emerged. Small excesses of L-amino acids have been observed in meteoritic samples such as from the Murchison meteorite (Cronin and Pizzarello 1997; Koga and Naraoka 2017) and provide the only natural example of molecular asymmetry measured outside of the biosphere. Current space missions such as JAXA’s Hayabusa2 (Watanabe et al. 2017) and NASA’s OSIRIS-Rex (Lauretta et al. 2017) have returned or will return asteroid samples to Earth, allowing for more detailed, uncontaminated analysis in the early 2020s.

Other postulated sources of an initial asymmetry which might have seeded life’s homochirality include the electroweak interaction (Cline 2005); the influence of an asymmetric environment, such as certain mineral surfaces (Hazen 2004; Im et al. 2020), crystal solutions (Hananel et al. 2019); enantiomeric excesses of specific amino acids (Jiang et al. 2014); effects of circularly polarized light (Garcia et al. 2019); random statistical fluctuation (Frank 1953; Ribó and Hochberg 2019), particularly within large chemical systems containing high numbers of chiral species (Laurent et al. 2021); antineutrinos from supernovae (Famiano et al. 2021); noise (Jafarpour et al. 2015); or punctuated combinations of natural events (Gleiser et al. 2008). Most of these sources of asymmetry produce only a small enantiomeric excess, and some type of amplification mechanism is therefore required to achieve the

complete chiral symmetry breaking as observed in living systems (Blackmond 2020).

Amplification can occur through ► **autocatalysis**, when one enantiomer acts as a catalyst for its own formation while simultaneously suppressing the formation of the other enantiomer (Soai et al. 2014). While there are many theoretical examples, the only experimental verification of autocatalysis resulting in symmetry breaking is the Soai reaction, where a small enantiomeric excess of substrate catalyzes the formation of a chiral product, which autocatalytically leads to further chiral product formation (Soai et al. 1995). Amplification has also been demonstrated to occur through crystallization processes (Dutta and Gellman 2017) and phase behavior (Blackmond and Klussmann 2007), and has been proposed to occur via polymerization in the initial stages of life (Chen and Ma 2020).

However, no mechanism for the origin of life's homochirality has been conclusively determined. Due to the universal nature of life's observed homochirality, the question of chirality in potential extraterrestrial biochemistries is pertinent to astrobiological searches for life. Homochirality is therefore among the leading candidates for biosignatures within the solar system (Glavin et al. 2020) and extrasolar worlds (Avnir 2021).

Homology

David Moreira

Unité d'Ecologie, Systématique et Evolution
CNRS UMR8079, Université Paris-Sud 11, Paris, France

Keywords

Common ancestry · Phylogeny · Similarity

Definition

Homology, one of the key concepts in modern evolutionary biology, refers to the similarity between characteristics of organisms due to a common origin from a **common ancestor** (i.e., shared ancestry). Homology can be applied to organs and anatomical structures but also to molecular characters such as DNA sequences. When characters in different organisms are similar but they do not share a common evolutionary origin, they are called analogous (e.g., the wings of birds and insects) and they are the product of convergent evolution. The accurate distinction between true homologous characters and analogous ones is an essential step for phylogenetic analyses.

History

The biological concept of homology was first used by the French naturalist Étienne Geoffroy Saint-Hilaire (1772–1844) to describe anatomical similarities in animals (Saint-Hilaire 1818). Organs of different animal species occupying the same position and having similar connections with other organs were defined as homologous.

This approach allowed defining body plans that were common to very diverse species despite their apparent dissimilarity. Later on, homology studies were carried out in other organisms and, during the twentieth century, also to molecular characters, including DNA and protein sequences.

Overview

Homology is often confounded with similarity, which is erroneous. Homology is an absolute criterion: two characters (e.g., two genes) are homologous or not, namely, they derive from a common ancestral character (e.g., an ancestral [gene](#)) or not. This means that homology, in contrast with similarity, cannot be quantified, so that statements frequently seen in literature like “high homology” or “percent homology” are incorrect (“high similarity” and “percent similarity” would be the correct terms). Likewise, homology does not imply the maintenance of identical functions in different organisms. In fact, homologous structures can evolve to carry out different functions, such as the wings of bats versus the arms of other mammals. Genes derived from a common ancestral gene but carrying out different functions are very common. For example, enzymes involved in cell metabolism in many species, such as the lactate dehydrogenase, are used in animals also as structural proteins called crystallins to build up the lenses of eyes.

Although similarity is not a strict criterion to determine homology because of potential problems of convergent evolution (e.g., integral membrane proteins tend to accumulate hydrophobic amino acids, artificially increasing the similarity of sequences), it is often used to suggest homology between DNA and protein sequences (Zuckerandl and Pauling 1965). In those cases, probabilistic criteria are commonly used to avoid considering as homologous sequences that resemble each other by chance. The correct identification of homologous sequences is an essential prerequisite for molecular phylogenetic analyses, to avoid the use of convergent characters that lead to the reconstruction of artifactual trees. There are two major types of homologous sequences:

orthologous (those that diverge following the divergence of species) and [paralogous](#) (those originated from gene duplication) ones (Fitch 2000).

Definition

A Hoogsteen Pair is a non-canonical/non-Watson–Crick hydrogen-bonded motif observed in nucleic acids.

Two nucleosides from two different nucleic strands, or from distal regions of the same strand, can be held together by Hoogsteen base pairing. Hoogsteen base-pairs often involve the N⁷ position of purine bases as H-bond acceptors and the C⁶ exocyclic amino group of adenine residues as H-donors, which then bond with the Watson–Crick surface of pyrimidine bases.

Karst Hoogsteen discovered the eponymous motif after observing a crystal structure of a nucleic acid complex in which analogues of adenine and thymine formed base pairing motifs with a different geometry from the Watson and Crick motif.

Hoogsteen pairs have considerably different geometries from Watson–Crick base pairs and consequently distinct behavior. Hoogsteen base pairs exist transiently in some DNA molecules in thermal equilibrium with standard Watson–Crick base pairs. They are also observed in protein–DNA complexes and G-quadruplexes.

Definition

Hopanes is a class of pentacyclic compounds derived from bacteriohopanepolyols (hopanoids) via diagenetic degradation and thermal maturation. The hopane structure is a saturated hydrocarbon (Fig. 1). Hopanes are molecular fossils of bacterial lipids that serve to adjust membrane permeability and fluidity as well as other adaptations to extreme habitats.

Hopanes are observed in carbonate and shale sediments as old as 1.65 Ga. They are common of, but not limited to, oceanic, lacustrine, hydrothermal environments throughout geological history but are markedly abundant in sediments from some extreme depositional settings, such as the Cretaceous oceanic anoxic events (OAEs). The

Hopanes, Geological Record of, Fig. 1 Core structure of hopanes composed of C–C bonds (lines) and saturated with hydrogen atoms (not shown). The key stereochemical variants occur at C-17, C-21, and C-22 positions. Additional methylation is common at C-2 and C-3. Other structural variants are missing methyl groups. *R* = H, methyl, ethyl, *n*-propyl, *n*-butyl, or *n*-pentyl group

distribution of hopane structures in a kerogen, oil, and bitumen often reflects the degree of thermal maturity and correlates to relative carbonate versus clay content. Further, various hopane distributions can be indicative of source matter or depositional environment.

[UAE's Emirates Mars Mission](#)

Definition

The UAE's Emirates Mars Mission, dubbed the Hope Probe, is confounding our scientific understanding of Mars' atmosphere, studying the distribution of hydrogen and oxygen in the planet's exosphere and sharing unprecedented findings with the world. Equipped with three instruments, the Hope Probe aims to provide the first complete picture of the Martian atmosphere and build local capabilities in science and technology as the UAE creates a knowledge and innovation-driven economy.

Overview

Emirates Mars Mission (EMM) is the UAE's first interplanetary mission. It was designed to orbit Mars and study the dynamics in the Martian atmosphere on a global scale, and on both diurnal and seasonal timescales. Using three state-of-the-art scientific instruments on board the spacecraft, EMM will provide a set of measurements fundamental to an improved understanding of circulation and weather in the Martian lower and middle atmosphere. Combining this data with the monitoring of the upper layers of the atmosphere, EMM measurements will reveal the mechanisms behind the upward transport of oxygen and hydrogen. The data that is being collected by the mission is considered the most comprehensive measurements of both the weather system in Mars and its correlation with atmospheric loss. The Hope Probe launched in July 2020, and arrived at Mars on the February 9, 2021. The first batch of science data was released to the public in October 2021.

EMM represents the Arab world's first interplanetary exploration and is the result of 15 international collaborations with global partners, including the University of Colorado Boulder's Laboratory for Atmospheric and Space Physics, Arizona State University, and the University of California, Berkeley.

His Highness Sheikh Mohammed bin Rashid Al Maktoum, UAE Vice President, Prime Minister and Ruler of Dubai, called it the Hope Probe to

send a message of optimism for millions of young Arabs. It will usher in a new era of scientific discovery for the good of humankind and has already made history.

Hope Mission

The Arab world's first interplanetary mission was announced in 2014. It took just 7 years to go from concept to launch. The Hope Probe successfully entered the Red Planet's orbit in 2021, coinciding with the 50th anniversary of the UAE, which became an independent nation on December 2, 1971.

While the UAE's space sector is young and developing, it boasts more than a decade of earth observation experience. Among the early satellites developed by the UAE include DubaiSat-1, the country's first probe which was launched in 2009, and KhalifaSat – the first to be 100% designed in the Emirates.

EMM represents a major step forward in the country's technical and scientific capabilities. It was conceived to disrupt and accelerate the UAE's space industry by shaping a scientific community and boosting Emirati advanced engineering and space science research and innovation.

Hope Probe began its journey to Mars from the Tanegashima island in Japan on July 20, 2020, during the height of COVID-19 pandemic. The mission had a 30-day launch window between July 15 and August 12, 2020. On the launch day, the Hope Probe lifted off on a Mitsubishi H-IIA rocket on a trajectory that took it over the Pacific Ocean.

During the first stage, the rocket boosters were expended, as the rocket accelerated away from the Earth. This was followed by jettisoning the fairing as it no longer needed to protect Hope Probe from the Earth's atmosphere. In the second stage, the rocket jettisoned and put the Hope Probe into Earth's orbit. It stayed here until the exact alignment with Mars, after which it was pushed on its trajectory toward the Red Planet. Following this, with the right direction and velocity of 11 km/s, the upper stage gently deployed the Hope Probe.

Traveling 493,500,000 km to Mars, Hope Probe fired all six of its Delta-V thrusters for 27 min to decelerate enough to be swept up by the Red Planet's orbit. It entered Mars' orbit on February 9, 2021 – becoming the first Arab nation to complete this feat of science, technology, engineering, and innovation.

Following its insertion into Mars orbit, Hope Probe entered the next phase of transitioning to science orbit, which saw Hope Probe moved away from its elliptical capture orbit (between 1063 km to 42,461 km from Mars' planetary surface) to a wider scope of 20,000 km by 43,000 km. The transition to the science orbit marked the start of Hope Probe's science mission.

Orbiting Mars every 55 h, the Hope Probe is now monitoring weather changes throughout the day, across the planet, during all seasons. It also monitors the distribution of hydrogen and oxygen in the upper portions of Mars' atmosphere, known as the exosphere. It will also explore the link between weather changes in Mars' lower atmosphere, with the loss of hydrogen and oxygen from the upper layers of the exosphere. For the first time, this will allow scientists to study the link between weather change and atmospheric loss – a process that may have been responsible for Mars' transition, over billions of years, from a thick atmosphere capable of sustaining liquid water on the surface, to the cold, thin, arid atmosphere we see today.

The Hope Probe will study the atmosphere from an orbit of 20,000 km periapsis and 43,000 km apoapsis, with an orbital inclination of 25 degrees. No other Mars spacecraft has had such an orbit; most orbit at a single local time that allows the atmosphere to be measured at only one time of day. It carries three state-of-the-art instruments on board: Emirates eXplorer Imager (EXI), a camera that captures both high-resolution digital color images as well as a few ultraviolet measurements that observe ice and stratospheric ozone in the lower atmosphere; Emirates Infrared Spectrometer (EMIRS), an infrared spectrophotometer to measure temperature and the distribution of dust, water vapor, and ice clouds; and the Emirates Mars Ultraviolet Spectrograph (EMMUS), a UV spectrophotometer to study oxygen and

carbon monoxide levels in the planet's thermal layer, as well as the presence of hydrogen and oxygen in the upper atmosphere.

In 2021, EMM published Hope Probe's first batch of scientific data. The unique data on Mars challenges our existing conception of how the planet's atmospheric gases behave and interact. These observations reveal variations in the concentrations of both atomic oxygen, hydrogen, and carbon monoxide in the atmosphere. Within the data are unique observations of the discrete aurora on Mars and well as data that indicates higher than expected levels of atomic oxygen in the upper atmosphere of Mars. The data is due to release on a 2–3 month cadence to scientists globally.

The unprecedented insights provide a new and unique understanding of the Martian climate.

Hope Probe will continue its scientific journey for a full Martian year (687 Earth days, or about 2 years). If things go well, EMM has an optional 2-year extension to keep the spacecraft in Mars until 2025 to continue its pioneering work.

Horizontal Branch

Nikos Prantzos
Institut d'Astrophysique de Paris, Paris, France

Definition

The horizontal branch (HB) is the region of the Hertzsprung-Russell diagram occupied by evolved stars – after the ▶ [red-giant](#) stage – of low mass and low metallicity (abundance of

elements heavier than He less than 0.1 that of the Sun), during their central He-burning (He-fusion) phase. The HB is observed in globular clusters, whereas in open clusters (having approximately solar ▶ [metallicity](#)), stars are confined to the bottom of the red-giant branch during core He burning. Metallicity is the key factor explaining that difference (low-metallicity stars have lower opacities and are hotter), but other factors (composition, age, rotation, envelope mass) appear to affect the morphology of the HB.

Gas-grain chemistry · Ice evaporation ·
Interstellar molecules · Protostar

Synonyms

[Hot molecular core](#)

Definition

Hot cores are transient regions surrounding massive ► [protostars](#) very early in their evolution. Similar regions are identified around low-mass protostars and are called hot corinos. Hot cores were originally identified as high-temperature regions near massive ► [protostars](#) which showed high abundances of ammonia.

Overview

Hot molecular cores and hot corinos are characterized physically by high gas densities ($>10^6 \text{ cm}^{-3}$) and elevated temperatures of both gas and dust ($\sim 100\text{--}500 \text{ K}$). The gaseous chemical composition is distinct from that of cold molecular clouds, due to evaporation of ice mantles from dust grains, and contains many complex organic molecules. The high temperatures are produced by the luminosity of the protostar and the protostellar accretion disk. Shock waves may also play a chemical role in both heating the gas and in ► [sputtering](#) icy grain mantles back into the gas.

Hot cores are chemically rich and display the products of interstellar grain-surface chemistry in the gas phase. For this reason, they can be used to probe catalytic processes on dust grains. Among the species found in them are methanol, ethanol, dimethyl ether, ethyl methyl ethyl, methyl formate, ethyl formate, ketene, formaldehyde, acetaldehyde, formic and acetic acid, glycolaldehyde, ethylene glycol, several nitriles, and possibly glycine. Some of these organics (e.g., the ethers) could also be formed in the hot gas from those intermediaries formed on and sublimated from the icy mantles on the dust.

Hot cores eventually evolve into ultracompact H II regions as the UV radiation from the massive central star breaks out into the surrounding environment. In the case of low-mass protostars, the hot corino phase is probably terminated by dissipation of the protostellar envelope by accretion onto the circumstellar disk and by powerful outflows.

Hot Corino

Steven B. Charnley
Solar System Exploration Division, Code
691, Astrochemistry Laboratory, NASA Goddard
Space Flight Center, Greenbelt, MD, USA

Definition

The name hot corino has been given to the immediate environment of a low-mass protostar in which the gas and dust have been heated by the protostellar radiation and shock waves. Hot corinos are characterized by large abundances of complex molecules and high ► [deuterium](#) fractionation ratios, both indicative of sublimation of ► [interstellar ices](#).

History

Hot corinos were so named by Cazaux et al. (2003) because of the similarity with the hot cores found around high-mass protostars.

Hot Spring Microbiology

Felipe Gomez

Centro de Astrobiología (CSIC/INTA), Instituto Nacional de Técnica Aeroespacial, Torrejón de Ardoz, Madrid, Spain

Definition

Hot spring microbiology refers to the study of microorganisms associated with hot springs. Hot springs are characterized by hydrothermal systems that constantly release geothermal gases and fluids from the subsurface due to water sources in contact with shallow magma formations. Many hot springs have temperatures at or near boiling point; thus, microorganisms from these environments are hyperthermophilic or thermophilic and phylogenetically very diverse, including ▶ [archaea](#), bacteria, and viruses. Water chemistry and pH can vary dramatically in these environments. ▶ [Methanogens](#) that belong to the Archaea group and grow at temperature between 80 and 90 °C are present in these systems. Cyanobacteria are often the dominant or sole photosynthetic organisms present in hot springs. Species of *Thermotoga* capable of growing at 90 °C have been isolated in hot springs and marine hydrothermal vents. Thermophilic Crenarchaeota have been isolated from hot, sulfur-rich solfataras, and some methanogenic archaea have also been identified in these environments. Viruses are represented by extreme thermophiles, bacteriophages, living up

to 85–90 °C. These microorganisms play important roles in the carbon, sulfur, and iron cycles in hot spring ecosystems.

Hot Vent Microbiology

Felipe Gomez

Centro de Astrobiología (CSIC/INTA), Instituto Nacional de Técnica Aeroespacial, Torrejón de Ardoz, Madrid, Spain

Synonyms

[Hydrothermal vent microbiology](#)

Definition

Hot vent microbiology refers to the microbial diversity associated with underwater hot springs known as hydrothermal vents. Chemical analysis of hydrothermal fluids shows large amounts of reduced inorganic materials, including H₂S, Mn²⁺, H₂, NH₄, and CO. The system is based on chemolithoautotrophy (nitrifying metal- and sulfur-oxidizing microorganisms and ▶ [methanogens](#)). Hydrothermal vents combine several extreme conditions including temperature (up to 380 °C), pressure (20 MPa at 2,000 m), and pH (plumes of pH 2.5), in the absence of sunlight, all of which determine that primary producers have to use chemical energy for CO₂ fixation. The temperature gradient from the surrounding

water that is heated up to 300–400 °C by magma that pours out through cracks in the lithosphere to seawater, which remains around 2 °C, creates a very unstable environment. Chimney growth from mineral precipitation when hydrothermal fluids come into contact with cold seawater (black smokers) serves as a substrate for associated microorganisms that can metabolize sulfur and metal sulfide compounds. The seafloor vents have important astrobiological connotations because they are considered interesting models for the origin of life on Earth as well as potential habitats on other planetary bodies such as Jupiter's moon, Europa.

Hoyle, Fred

Fernando B. Figueiredo
CITEUC, University of Coimbra, Coimbra,
Portugal

History

Fred Hoyle (1915–2001) besides a scientist was also an English national figure, born in June 24, 1915, at Gilstead, Bingley West Yorkshire,

England. He graduated at Cambridge University, where he enrolled in 1933. Despite having arrived at Cambridge's Pembroke College with serious gaps in his mathematical background training, a fact he quickly surpasses, Fred Hoyle would prove to be a brilliant student winning the Mathematical Tripos in 1936 and being awarded with the Mayhew Prize as the best student in applied mathematics. During the Second World War he worked for the Admiralty, returning to Cambridge in 1945 as lecturer in mathematics (1945–1956). Between 1957 and 1972 Fred Hoyle will occupy the Plumian chair, one of the major Professorships in Astronomy and Experimental Philosophy at Cambridge's University, and became the founder director of the Institute of Theoretical Astronomy (1967–1972).

Throughout his very active and long scientific live Hoyle will win many awards. He was elected Fellow of the Royal Society of London in 1957 and foreign associate of the US National Academy of Sciences, and he was president of the Royal Astronomical Society between 1971 and 1973, which had awarded him its gold medal in 1968. In 1974 he awarded the Royal Medal of the Royal Society and in 1997 the Crafoord Prize from the Swedish Academy of Sciences. In 1977 he won the Klumpke-Roberts Prize from the Pacific Astronomical Society, and in 1994, along with Martin Schwarzschild, he would win the Balzan Prize. Hoyle was one of the main responsible in the planning and construction of the Anglo-Australian Telescope when he chaired the Science Research Council's advisory committee. Queen Elizabeth II made him knight in 1972.

In astronomy Hoyle's works spans from astrophysics and particle physics to cosmology. Fred Hoyle was the first, in 1946, to establish in solid bases the concept of stars' nucleosynthesis. In 1957, in a joint article with Margaret Burbidge, Geoff Burbidge, and Willy Fowler, Hoyle will publish in the *Reviews of Modern Physics* the famous B2FH paper (the name comes from the last initials of the authors). In this work entitled *Synthesis of the Elements in Stars*, the authors give an explication for the existence in the universe of elements heavier than helium, showing that all of the elements from carbon to uranium

could be produced by nuclear processes in stars, starting with the hydrogen and helium. Hoyle showed that the new young stars are already formed with these heavy elements, which were created in older ones. He also established the theory that other rare elements could be explained by supernovae.

Although ironically the term “big bang” was coined by Hoyle himself in a BBC’s radio show, the truth is that Hoyle did not accept the theory of a primordial explosion as being at the origin of the universe and proposes a model alternative, the Steady State Theory. Hoyle’s name is intimal related to the concept of continuous creation of matter in the universe and to the field equations that achieved this result. In an attempt to adapt his primitive ideas to the measurement results on the background radiation, which over the years were being made, he will publish, coauthored with Burbidge and Narlikar, a book, *A Different Approach to Cosmology* (Cambridge University Press, 2000), presented an alternative to the Big Bang, by employing an oscillating and expanding steady-state universe.

In 1962 he started a famous collaboration with Nalin C. Wickramasinghe on the carbonaceous nature of interstellar dust and interstellar biology. The developments achieved by both will lead them to postulate the organic theory of cosmic dust, which states among other things that the seeds of life (i.e., the basic chemicals of DNA replication), including disease viruses, periodically fall from space transported by meteorites. To Hoyle life on Earth couldn’t have arisen by chance in a primordial soup; he favored and popularized a view called panspermia, the notion that life originated in space and was driven to Earth by electromagnetic radiation pressure.

Most of his controversial ideas were exposed in a lot of his popular non-fiction and science fiction books, including *Frontiers of Astronomy* (1955), *Men and Materialism* (1956), *Star Formation* (1963), *Galaxies, Nuclei and Quasars* (1965), *The Relation of Physics and Cosmology* (1973), *Ten Faces of the Universe* (1977), and *On Stonehenge* (1977). In 1994 he published his autobiography, *Home Is Where the Wind Blows*. Besides books Fred Hoyle also wrote some plays, television stories and A for Andromeda

serial, and an opera, *Alchemy Of Love*, or the *Daemon Servant’s Retribution*, which premiered in New York in 1969.

Synonyms

[High-performance liquid chromatography](#); [High-pressure liquid chromatography](#); [LC](#); [UHPLC](#)

Definition

HPLC is an efficient method of liquid–solid column chromatography. Using a stationary phase composed of small (3–10 μm) beads increases separation efficiency but requires pumps to force the

mobile phase through the column at pressures >300 bar. Ultra-HPLC (UHPLC) uses $<2\text{ }\mu\text{m}$ particles and pressures $>1,000$ bar. Unlike gas chromatography, the composition of the mobile phase is often varied with time while the column temperature is held constant. Reverse-phase HPLC uses a hydrophilic mobile and hydrophobic stationary phase, the opposite of normal-phase HPLC. HPLC is suited for coupling with different detectors, particularly in so-called hyphenated techniques, such as HPLC coupled to mass spectrometry (LC-MS).

[Hubble Space Telescope](#)

Definition

The Hubble Space Telescope (HST) is a NASA space observatory (Fig. 1) with a 2.5-m-diameter primary mirror operating in ultraviolet, visible, and infrared light. Launched in 1990, the HST was serviced five times by the

space shuttle and is still in operation. The 11,000-kg spacecraft is placed in low Earth orbit at an altitude of about 575 km. The data archiving and the scientific operations are managed by the Space Telescope Science Institute in the name of the scientific consortium consisting of numerous universities and institutions. The ► [European Space Agency](#) contributes through various participation up to 15% of the total cost.

History

From 1970 to 1978, US astronomers and NASA deployed an intense lobbying effort toward US congressmen to have the Large Space Telescope funded. The decision was taken after the decision of the European Space Agency to support this effort. Originally slated to be launched in 1983, technical delays made it almost ready only by 1986. The Challenger accident then grounded the Space Shuttle fleet for almost 3 years. The telescope had to be kept in a clean room, powered up, and purged with nitrogen. These operations were costing about \$6 million per month, pushing the overall costs of the project up to \$2.5 billion by the time of the launch. During this time period, the engineers performed extensive tests, swapped out a possibly failure-prone battery, and made several technical improvements. The ground software controlling Hubble was just ready by the 1990 launch.

Once in space, the first images were not as sharp as expected and demonstrated a defect in the primary mirror curvature. This flaw was mainly impairing the observation of faint objects and the cosmology program. The origin of the flaw was clearly identified and a corrective instrument was designed. Awaiting the repair by the shuttle mission in December 1993, HST performed many valuable observations for astronomers.

Since then and with the following four maintenance flights, the HST has delivered unprecedented results in all fields of astronomy. The overall US expenditure for the HST is estimated at between \$4.5 and \$6 billion, with Europe's financial contribution at about €600 million.

HST, Fig. 1 The Hubble Space Telescope imaged by the shuttle during the last servicing mission in 2009 (Credit NASA)

Overview

The Hubble Space Telescope was sent into orbit on April 24, 1990, by the Space Shuttle Discovery. This 11,000-kg telescope was serviced five times by the space shuttle in its working orbit at an altitude of about 575 km. The telescope was built by NASA with a significant contribution from ESA. It is operated by NASA and the data are archived at the Space Telescope Science Institute in Baltimore, USA. The Hubble's spectral range extends from the ultraviolet, through the visible, and into the near-infrared. Hubble's primary mirror is 2.4 m in diameter, which is not large by ground-based standards. The instruments as well as the avionics and hardware were upgraded and exchanged during the five successive servicing missions. Now, and up to the end of the mission, the HST is equipped with five instruments. The Advanced Camera for Surveys (ACS) was installed in 2002, improving the field of view and the light sensitivity. It is working with the newly installed Wide Field Camera (WFC3). The Cosmic Origins Spectrograph (COS) instrument is an ultraviolet spectrograph optimized for observing faint point sources with moderate spectral resolution. The Near-Infrared Camera and Multi-object Spectrometer (NICMOS) is the infrared instrument able to see through interstellar gas and dust. Finally, the Space Telescope Imaging Spectrograph (STIS) separates light into component wavelengths, acting much like a prism. All these instruments are placed at the focal plane of the telescope.

Key Research Findings

The HST was built and designed to image far, faint galaxies. This fossil light reveals how the Universe looked in the remote past and how it may have evolved with time. The Hubble Deep Fields gave a clear glance back to the time when galaxies were forming. Deep field observations require long-lasting pointing accuracy to a selected region of the sky. Deeper observation requires a longer exposure time, while the fainter objects become visible on the images. The first deep fields gave new insight about the early Universe, revolutionizing modern astronomy. The HST has harvested outstanding results in many fields of astronomy, like the calculation of the Hubble constant, the evaluation of the age of the Universe, and the astrophysics of objects such as quasars and super-massive black holes in the centers of galaxies. The systematic surveys were also used to detect gravitational lenses and map the distribution of dark matter in some portions of the Universe. For astrobiology, the Hubble Space Telescope has contributed to the imaging of the clouds of gas and dust where new stars are forming. Data collected from the Orion Nebula are giving new insight into these processes. The detected dust disks around newborn stars could be the beginning of planetary systems. Hubble performed the first detection of an atmosphere around an extra-solar giant planet, which orbits a Sunlike star (► [HD 209458b](#)) located 150 light-years away in the constellation Pegasus.

Hubble made also unique, repeatable observations of the surfaces of the planets and objects of our Solar System: imaging the dust storms on Mars, preparing for the flyby of asteroids like Vesta by the Dawn mission, or recording “live” the diving of the comet Shoemaker-Levy into the atmosphere of Jupiter (see Fig. 2).

For astrobiology, HST observations of several celestial bodies of the Solar System in all the wavelengths available evidenced auroras and rings for the large gaseous planets, complemented the observations from the orbit to decipher the weather system on Mars, discovered new moons of Pluto and other dwarf planets, performed numerous discoveries of Kuiper belt objects. HST also witnessed volcanic emission from Jupiter’s moon Io and revealed water plumes from Europa and another Jovian moon.

HST is also designed to dig in-depth into the origin of the universe and of the planetary systems. The high spatial resolution images for the Orion Nebula demonstrated that protoplanetary disk systems are commonly formed around stars. HST contributed to the discovery of some extra-solar planets through transits. The spectroscopic observations with Hubble of extrasolar planets

HST, Fig. 2 This natural-color image of Jupiter displays at the bottom right debris from a comet or asteroid that plunged into Jupiter’s atmosphere and disintegrated (Credit: NASA, ESA, Michael Wong [Space Telescope Science Institute, Baltimore, MD], H. B. Hammel [Space Science Institute, Boulder, CO], and the Jupiter Impact Team)

and their parent stars characterized some planetary atmospheres, evidenced of the presence of clouds, and identified for some a few planets, major atmospheric compounds such as methane, titanium oxide, and water.

Future Directions

The James Webb Space Telescope (► [JWST](#)), launched on December 25th, 2021, is placed in a halo orbit at the Lagrangian point L2. It is considered as the successor of the HST while it will operate instruments using different wavelengths.

Hubble, Edwin

Fernando B. Figueiredo
CITEUC, University of Coimbra, Coimbra,
Portugal

History

Edwin Powell Hubble (1889–1953) was an American astronomer known by his works on galactic and extragalactic astronomy. His works provided

the first persuasive observational evidence that the Universe is expanding.

In 1929, with data collected from the best telescope of that time, the 100-in. telescope of the Mount Wilson Observatory, he showed that galaxies are moving away from Earth with a speed proportional to their distance according to the law, $v = H_0 \times d$, where v is the recession velocity of a galaxy at a distance d and H_0 is the value for the Universe expansion rate at the current epoch. Hubble's initial value for H_0 (now called the Hubble constant) was calculated to be approximately $500 \text{ km s}^{-1} \text{ Mpc}^{-1}$.

The Hubble Space Telescope, a satellite observatory orbiting Earth, launched by NASA's Space Shuttle mission STS-31 on April 24, 1990, is continuing the work begun by Hubble himself to study and map our Universe and helping to determine the Hubble constant to an accuracy of $\pm 10\%$; the actual H_0 value is $72 \pm 8 \text{ km s}^{-1} \text{ Mpc}^{-1}$.

Huronian Glaciation

Andrey Bekker

Department of Earth Sciences, University of California, Riverside, Riverside, CA, USA

Department of Geology, University of Johannesburg, Johannesburg, South Africa

Keywords

Paleoproterozoic · Ice ages · Snowball earth · Rise of atmospheric oxygen

Synonyms

[Paleoproterozoic ice ages](#); [Paleoproterozoic Snowball Earth](#)

Definition

The Huronian glaciation is the oldest series of protracted climatic refrigeration events that extensively affected Earth. It occurred between 2.45 and 2.22 Ga in association with the rise of atmospheric oxygen. Three glaciations of that series, the classical Huronian ice ages, are bracketed in time between ~ 2.45 and 2.32 Ga, with the oldest glaciation at ~ 2.43 Ga (Gumsley et al. [2017](#)); the fourth event, recognized so far only in South Africa, is ~ 2.22 Ga in age. During these events, glaciers covered continents, extended to low latitudes, and reached to sea level. The ice ages were followed by a protracted time interval with greenhouse (warm and humid) conditions. The name is derived from the Huronian Supergroup exposed on the north shore of Lake Huron in Ontario, Canada, between Sault Ste. Marie, Sudbury, and Cobalt.

History

The Huronian glacial deposits were first recognized by Coleman ([1907](#)) in the northeastern part of the Huronian Basin in Ontario, Canada; just a year after a poorly sorted conglomerate with scattered pebbles and cobbles, some striated and faceted, was described in the Northern Cape Province of South Africa by Rogers ([1906](#)), who interpreted it to be glacial in origin. Blackwelder in 1926 inferred glacial origin for the Headquarter Formation of the Snowy Pass Supergroup in the Medicine Bow Mountains, SE Wyoming, which he correlated to the Huronian Supergroup of Ontario, Canada. Almost 20 years later, Pettijohn ([1943](#)) described tillite in a correlative to the Huronian Supergroup succession of Michigan, USA. Young ([1970](#)) synthesized all available by that time data and inferred glacial influence on Paleoproterozoic successions in Wyoming, Michigan, Quebec, and Nunavut. Shortly thereafter, Paleoproterozoic glacial deposits were for the first time recognized in Western Australia (Trendall [1976](#)), described in more details in South Africa (Visser [1971](#)), and inferred in the Dead River Storage Basin of Marquette County,

MI, USA (Puffett 1969). Although the presence of Paleoproterozoic glacial deposits in Fennoscandia was originally discussed by Eskola (1919), they were not described and documented in detail until recently (Marmo and Ojakangas 1984; Strand and Laajoki 1993). In Antarctica, the 2.50–2.45 Ga Ruker Series contains diamictite above thick banded iron formation associated with mafic volcanics (Mikhalsky et al. 2006; Phillips et al. 2006), offering a comparison with the Meteorite Bore Member of the Turee Creek Group in the Hamersley Province of Western Australia (see below). All other reported cases of Paleoproterozoic glacial deposits were either not confirmed by subsequent sedimentologic studies or turned out to be significantly younger and not correlative with the Huronian glaciations (e.g., Sausar Group, India: Mohanty 2006 vs. Mukhopadhyay et al.

2020; Hutuo Group, China: Chen et al. 2019 vs. Chen et al. 2018 and Du et al. 2011).

Overview

Paleoproterozoic glacial deposits are now confirmed in a number of basins in North America (Figs. 1 and 3), Western Australia (Meteorite Bore Member of the Turee Creek Group), South Africa (Pretoria and Postmasburg groups), and Fennoscandia (Sarioli informal group in Finland and in Karelia and Kola Peninsula, Russia). Evidence for glaciation is plentiful in these successions and includes varves with dropstones; striated, flat-iron-shaped, and faceted pebbles; striations in the underlying basement; exotic stones in diamictite (Fig. 2); extensive

(a) Dropstone in finely laminated mudstone of the Pecors Formation, Huronian Supergroup, north of Quirke Lake; hammer for scale is 40 cm long. (b) Large dropstone in laminated matrix of the Gowganda Formation in Cobalt area; hammer is 70 cm long. (c) Dropstone of granite in finely laminated matrix of the Gowganda Formation, north of Elliott Lake; coin is

2.8 cm in diameter. (d) Red sandstone sandwiched between glacial diamictites of the Gowganda Formation, north of Elliott Lake, person for scale. (e) Molds of gypsum in red-colored siltstone from postglacial succession in Michigan (HW 480; Kona Dolomite); coin is 2.8 cm in diameter for scale. (f) Cross-bedded red-colored mudstone-siltstone in the upper part of the Gowganda Formation deposited in oxygenated deltaic setting, Cobalt area; hammer for scale is 70 cm long

development of diamictite not controlled by syn-sedimentary faults; till pellets; and chemical and mineralogical immaturity of conglomerate matrix (cf. Young 1970). The Huronian Supergroup contains three glacial units (Fig. 3), whereas other successions, except for the Snowy Pass Supergroup and Snowy Pass Group in Wyoming, USA, contain only one or two, making intra- and

intercontinental lithostratigraphic correlations difficult. It seems likely that four glacial events occurred in the Paleoproterozoic, but their regional or global extent is not well constrained. Paleomagnetic data are as yet scarce; however, they suggest low-latitude position of glaciated landmasses (e.g., Evans et al. 1997; Gumsley et al. 2017), whereas sedimentologic data

Huronian Glaciation, Fig. 3 Generalized stratigraphic sections of the Pilbara, Griqualand West/Transvaal and Huronian successions, highlighting the stratigraphic disposition of Paleoproterozoic global glaciations, C- and S-isotope chemostratigraphy, and published geochronology (after Bekker et al. 2020, 2021 with additional information on mass-independent fractionation of sulfur (MIF-S) and mass-dependent fractionation of sulfur (MDF-S) from Poulton et al. 2021). Neither stratigraphic thickness nor

absolute age are implied by the thickness of units in stratigraphic columns, whereas gaps along stratigraphic sections are hiatuses on unconformities. Bubblee is the Bubhawalaye Formation; Q1, Q2, and Q3 are respectively Quartzite 1, 2 and 3; MBM is the Meteorite Bore Member. The exact stratigraphic position of the transition from MIF-S to MDF-S is uncertain for the Huronian Supergroup and therefore not shown

indicates that ice extended to sea level in these regions (e.g., Young 2004), inviting a comparison with the Neoproterozoic Snowball Earth glaciations.

Large igneous provinces were extensively emplaced before (2.5–2.45 Ga) and after (~2.22 Ga) the Huronian glaciations, but with the exception of the ~2.32 Ga mantle plume and few locally developed orogenic events (e.g., Arrowsmith Orogeny), the 2.45–2.22 Ga time interval is largely devoid of magmatic activity (cf. Partin et al. 2014). Tuff beds dated in the Huronian Supergroup, Canada, and the Pretoria Group, South Africa (Rasmussen et al. 2013), have finally bracketed the age of the Paleoproterozoic ice ages (Fig. 3). Three Huronian glaciations are all between ca. 2.45 and 2.32 Ga in age, whereas the youngest glaciation recorded by the upper Pretoria Group is ca. 2.22 Ga in age. These

data allow two tantalizing implications: (1) The Huronian ice ages lasted long; (2) there was a glacial event at ca. 2.22 Ga in South Africa, which, based on geochronological constraints, might correlate with glacial units of the Chocoday Group in Michigan, USA (Vallini et al. 2006). The Makganyene Diamictite of the Postmasburg Group of the Griqualand West basin (paleomagnetically pinned to low paleolatitudes; Evans et al. 1997) was recently geochronologically bracketed between ~2.46 and 2.43 Ga in age (see Fig. 3; Gumsley et al. 2017), potentially providing the best age constraint for the beginning of the GOE. Correlation of the glacial diamictite of the Meteorite Bore Member of the Turee Creek Group with the Huronian glacials remains uncertain; considering that the retro-arc setting of the Turee Creek Group evolved from a conformably underlying back-arc basin containing 2.5–2.45 Ga

Huronian Glaciation, Fig. 4 Secular carbon isotope variations in seawater and redox indicators for the oxidation state of the early Paleoproterozoic atmosphere-ocean system (Modified from Bekker and Holland 2012). Four blue vertical bars mark Paleoproterozoic glacial events; the dashed secular carbon isotope curve between 2.5 and 2.22 Ga emphasizes the uncertainty in this part of the curve; red filled shape is the Woolly Dolomite excursion (Bekker et al. 2016); the dashed bar for marine sulfate

evaporites after ~2.06 Ga indicates that sulfate evaporites again became rare in the Paleoproterozoic and Mesoproterozoic records after that time. Deposition of iron formations and Mn-rich deposits indicates anoxic conditions in deep waters. While deposition of iron formations does not necessarily require atmospheric oxygen and can be mediated by anoxygenic photosynthetic bacteria, Mn oxidation requires significant levels of atmospheric oxygen

Huronian Glaciation, Fig. 5 Stratigraphic column of the Huronian Supergroup in Ontario, Canada, that contains three glacial horizons and overlying units indicating extreme degree of weathering. Also shown are atmospheric

redox indicators, age constraints, and environmental and tectonic changes. (Modified from Bekker et al. 2006; Rasmussen et al. 2013)

banded iron formations (e.g., Krapež 1996), the most parsimonious interpretation is that it represents the oldest Huronian ice age.

In contrast to Neoproterozoic glacially influenced successions, carbonates with negative carbon isotope values directly overlying glacial diamictite are present only above the second glacial diamictite of the Huronian Supergroup and correlative glacially influenced successions elsewhere. There are carbonates with negative carbon isotope values stratigraphically immediately below the glacial diamictite of the Polisarka Sedimentary Formation on the Kola Peninsula of Russia (Brasier et al. 2013), which is considered

to correlate to the oldest Huronian glaciation (Bekker et al. 2020). Sequences immediately underlying Paleoproterozoic glacial diamictites include banded iron formations in Western Australia and South Africa and conglomerates with detrital pyrites and uraninites in North America and ► *Fennoscandia*, whereas overlying units contain red beds and sulfate evaporites (Figs. 2 and 4). Combined, these and other proxies for atmospheric and ocean redox state indicate a transition from the reduced to an oxygenated atmosphere and ocean during the Huronian glaciations (Bekker et al. 2004). It is generally accepted that the atmosphere before ~2.45 Ga was reducing and

contained significant (≥ 1000 ppm) levels of methane, an effective greenhouse gas. Rise of atmospheric oxygen in the early Paleoproterozoic decreased methane levels in the atmosphere and initiated climatic cooling leading to glaciation (Bekker et al. 2005). If this interpretation is correct, the Huronian glaciations represent a response of Earth system to the rise of atmospheric oxygen in association with carbon dioxide replacing methane as a main greenhouse gas (Bekker and Kaufman 2007). Lithologies overlying Paleoproterozoic glacial deposits suggest an extended period of enhanced chemical weathering in the aftermath of the Huronian glaciations (Young 1973), which could reflect warm and humid climate and acidic groundwaters during the Great Oxidation Event and Lomagundi Carbon Isotope Excursion (Konhauser et al. 2011; Bekker and Holland 2012) (Fig. 5).

Huxley's Conception on Origins of Life

Stéphane Tirard

Centre François Viète d'Histoire des Sciences et des Techniques EA 1161, Faculté des Sciences et des Techniques de Nantes, Nantes, France

History

Thomas Huxley (1825–1895) was a British biologist who endorsed Charles Darwin's theory of evolution. As a zoologist, physiologist, and evolutionist, Huxley explained his conceptions on nature of living matter in two important lectures: *The Physical Basis of Life* (1868) and *Biogenesis and Abiogenesis* (1870). In the first lecture, he described and analyzed the importance of the

protoplasm as the main constituent of cells. He wrote that the protoplasm, simple or with a nucleus, is the formal basis of all life, and he insisted on the fact that materialism is the best way to understand life. In the second text, he strictly rejected the spontaneous generation and described the debate on this matter. He suggested distinguishing two terms: *biogenis*, when living matter comes from living matter, and *abiobenesis*, synonymous of spontaneous generation, when living matter comes from inert matter.

Huygens

Therese Encrenaz
LESIA, Observatoire de Paris – Section de Meudon, Meudon, France

Definition

Christiaan Huygens (1629–1695) was born in The Hague (Netherlands). He studied law and mathematics in Leiden and then studied and built microscopes and telescopes. With his own telescope, he discovered ▶ [Titan](#), ▶ [Saturn's](#) biggest satellite, in 1655. In 1659, he found the explanation of the changing appearance of Saturn, due to its rings, which he published in *Systema Saturnium*. In 1656, he built the first pendulum clock with the objective of determining longitudes at sea. He developed in his *Traité de la Lumière* the first wave theory of light. His posthumous work, *Cosmotheoros*, published in 1698, deals with the nature of the universe and the habitability of other worlds. The probe of the Cassini-Huygens mission, which landed on Titan's surface on January 14, 2005, was named after him.

Definition

The Huygens probe was an atmospheric probe supplied by the European Space Agency (ESA) and part of the Cassini-Huygens mission to the ▶ [Saturn](#) system. The probe was named after the Dutch astronomer Christiaan Huygens who discovered ▶ [Titan](#), the largest satellite of Saturn, in 1655. It was designed to explore the environment of Titan, mainly its atmosphere, which makes Titan so unique. It was carried by the ▶ [Cassini](#) spacecraft. It entered Titan's atmosphere on January 14, 2005, and studied Titan for several hours during its descent and after its touchdown with the six instruments of its scientific payload (Table 1).

History

As early as 1982, an ambitious and international mission to explore the Saturn system was

initially proposed to ► [NASA](#) and ESA by a team of European and US scientists. A probe to specifically study Titan was identified very early in the study phase of the mission as a potential contribution of ESA. After a Phase A study, the Titan’s probe was selected in 1988 by the Science Programme Committee of ESA and named “Huygens” at that time. The selection of the ESA Huygens probe investigations, as that of the NASA Cassini orbiter, was done jointly by ESA and NASA and announced in the fall of 1990.

Overview

The Huygens probe (Lebreton and Matson [2002](#)) was one of the key elements of the Cassini-Huygens mission. It was provided by ESA and constructed by an industrial consortium, with Aerospatiale, Cannes, France (currently Thales Alenia Space), as the prime contractor (Clausen et al. [2002](#)). It was carried by the Cassini spacecraft from its launch, on October 15, 1997, to its release, on December 25, 2004. It separated from Cassini that day at 2:00 UTC with a relative speed of ~0.35 m/s. It entered Titan’s atmosphere on January 14, 2005, targeted to land on a southern-latitude site on Titan’s dayside. Protected by its heat shield (Fig. [1](#)), it experienced a strong aerobraking, with a velocity decreasing from 21,600 km/h during entry to less than

1400 km/h at 180 km altitude and only 290 km/h at 160 km. There the main parachute (8.3 m in diameter) opened and then discarded at about 110 km altitude and replaced by a small one (3 m in diameter). This last parachute allowed the probe to reach Titan’s surface before the Cassini spacecraft passed below the horizon of the ► [landing site](#). However, it was efficient enough to allow a low-velocity landing (5 m/s). The descent time in the atmosphere was close to 2 h and 30 min. The probe continued operating after landing on the surface for about 3 h. The first 1 h and 12 min of surface data was collected by Cassini, before it went out of the field of view of Huygens (Fig. [2](#)). The total mass of the probe was about 350 kg including the probe structure, support equipments, and 48 kg of scientific instruments. The probe was developed to explore Titan’s atmosphere, mainly from ~150 km altitude, down to the surface, and to, eventually, carry out some surface measurements, although it was not conceived to survive the surface impact. Huygens included six scientific experiments (Table [1](#)) to study the physical and chemical properties of the atmosphere and surface of Titan.

Huygens included a CD-ROM with about 100,000 messages collected by ESA between December 1996 and February 1997. Those messages included texts, drawings, audio messages, and signatures from tens of thousands of citizens from the planet Earth (Fig. [3](#)).

Huygens Probe,

Fig. 1 The back cover of the probe, with its gold-colored blanket, is attached to the Huygens probe, already inside its front shield (covered by heat-resistant tiles) (Credit: ESA (ID number: SEMJRJ2VQUD))

**Basic Methodology**

The energy on Huygens was delivered by five LiSO_2 batteries, capable of delivering more than 2 KWh. The data (housekeeping and scientific) were processed by a Command and Data Management Unit, which included a 16-bit microprocessor (running at 10 MHz). They were then sent to the Cassini orbiter in its solid-state memory with the Probe Data Relay Subsystem, which included S-band transmitters and circularly polarized transmitting antennas. The data were transmitted from Huygens to Cassini on two nearly redundant channels.

The ► [gas chromatograph-mass spectrometer \(GC-MS\)](#) (Niemann et al. 2002) included three GC columns, using dihydrogen as carrier gas, linked to a quadrupole mass spectrometer and a gas sampling system. The GC achieved the

separation of the different constituents of complex mixtures (atmospheric gases and heated or pyrolyzed aerosols from aerosol collector and pyrolyzer [ACP]). The MS allowed their detection and identification, with a mass range extending from 2 to 141 Da. The instrument was equipped with five ion sources feeding the mass analyzer sequentially. It also included an enrichment cell to concentrate trace gases and increase the limit of detection.

The ACP (Israel et al. 2002) was devoted to the in situ study of Titan's aerosols: their chemical composition and their distribution. It included a sampling system with a filter to collect atmospheric aerosols and an oven to heat the collected particles at different temperatures. Once the collecting phase was over, the filter was retracted inside the probe in the oven. Then the oven was isolated and the filter heated at different

H

Huygens Probe, Fig. 2 Artist's picture of the descent and landing of the Huygens probe on Titan on January 14, 2005 (Credit: ESA-D. Ducros (ID number: SEMF4XULWFE))

temperatures. The produced gases were then analyzed by the GC-MS instrument. Two samplings were carried out in the 130–35 km altitude and the 25–20 km altitude, respectively.

The Descent Imager and Spectral Radiometer (DISR; Tomasko et al. 2002), the only optical remote sensing experiment aboard Huygens, operated in the 0.3–1.7 μm wavelength range. It included photometers to look upward and downward, solar visible and infrared spectrometers, and several imagers. Its scientific objectives were to study the thermal balance, dynamics, and main composition of the atmosphere, as well as the distribution and properties of the aerosols. It was also able to provide many images and information on nature of the surface.

The Huygens Atmospheric Structure Instrument (HASI; Fulchignoni et al. 2002) was composed of several sensors to measure physical properties of the atmosphere: accelerometer, temperature and pressure sensors, a microphone, and an electric field sensor. One of the main goals of the HASI was to measure the vertical temperature/

pressure atmospheric profile from the mid-stratosphere to the surface of Titan.

The Surface Science Package (SSP; Zarnecki et al. 2002) was also a multisensor experiment to measure surface properties: temperature, thermal conductivity, heat capacity, speed of sound, dielectric constant, and index of refraction (if liquid). It included a force transducer to measure the impact deceleration.

The Doppler Wind Experiment (DWE; Bird et al. 2002) was designed to determine the direction and strength of the zonal winds in Titan's atmosphere. It was composed of a transmitter on the Huygens probe and a receiver on the Cassini orbiter, allowing Doppler tracking of the probe from the orbiter.

Key Research Findings

The whole Huygens operations worked perfectly, from the pre-entry in Titan's atmosphere to the landing (Lebreton et al. 2005, 2009; Owen 2005).

Huygens Probe, Fig. 3 The Huygens CD-ROM: front cover and CD (Courtesy of NASA/JPL/Caltech/ESA)

The latter was much smoother than expected, and the probe survived the impact and its instruments continued working for several hours on the surface. Only one problem was experienced: the loss of one of the two channels because of a programming error in its receiver. Consequently, no data were collected from this channel, which affected mainly the DWE experiment, but finally most of the data were recovered, thanks to Earth-based radio telescopes that were able to receive the weak radio signal from Huygens.

The scientific results of the Huygens instruments were first published in *Nature* in 2005 and then in two special issues of *Planetary and Space Science* (Raulin et al. 2007, 2008). They are also presented together with the Cassini data in a book devoted to Titan (Brown et al. 2009). The DISR (Tomasko et al. 2005) provided more than

Huygens Probe, Fig. 4 Channel networks, highlands, and dark-bright interface on the surface of Titan as seen by the DISR instrument on Huygens at 6.5 km altitude (Credit: ESA/NASA/JPL/University of Arizona – PIA07236)

Huygens Probe, Fig. 5 Image of Titan's surface where the Huygens probe landed taken by the DISR instrument on January 14, 2005. It shows pebble-sized objects, likely to be made of water ice (Credits: ESA/NASA/JPL/University of Arizona (PIA07232))

350 images and many spectra of Titan. Its images did not show any liquid ► [hydrocarbon](#) pool on Titan's surface, but dendritic structures formed by liquid which flowed in the past. It goes from brighter highland regions down to dark and flat lowlands (Fig. 4). They also showed that the Huygens landing site looked like a dry riverbed strewn with pebbles probably made of ► [water](#) ice (Fig. 5). The DISR infrared spectra of the surface suggested a mixture of water ice and organic compounds, including Titan tholin-like material. The DISR data also showed that haze particles in the atmosphere seemed continuously distributed from 150 km altitude to the surface, where the ► [methane](#) relative humidity reaches 50%. The HASI (Fulchignoni et al. 2005) determined the temperature, pressure, and density profiles of the atmosphere from 1400 km to the surface (Fig. 6). It detected an ionospheric layer in the low atmosphere, between 140 and 40 km, with a potential lightning signal. The SSP (Zarnecki et al. 2005) performed physical measurements just above and on Titan's surface. It evidenced a relatively soft

solid surface. The DWE team (Bird et al. 2005) was able to determine a high-resolution profile of the winds, including evidence for low-velocity winds below 5 km altitude, and to confirm the super-rotation of Titan. The GC-MS (Niemann et al. 2005) carried out a direct MS analysis of Titan's atmosphere from 146 km altitude down to the surface. It determined the concentration profiles of several atmospheric gases as a function of altitude and measured ► [isotopic ratios](#) and trace species. It detected ^{40}Ar as the main noble gas, with an abundance more than 100 times higher than that of ^{36}Ar . It measured $^{14}\text{N}/^{15}\text{N}$ and $^{12}\text{C}/^{13}\text{C}$ and D/H in the atmosphere and found values close to but smaller than the terrestrial values, except for D/H. It detected organic species on the surface, including ethane, cyanogen, and benzene. It also observed the presence of methane degassing on the surface. The ACP (Israel et al. 2005), using GC-MS as an analytical tool, was able to collect and pyrolyze atmospheric aerosols in the low stratosphere and mid-troposphere regions. It showed that the collected particles release NH_3

and HCN when heated at 600 °C, indicating that they are made of refractory organics, including ► **carbon** (C), ► **hydrogen** (H), and ► **nitrogen** (N) atoms (Fig. 7).

Applications

The Huygens probe was the first object launched by mankind that was able to softly land on a planetary object of the outer solar system. The Huygens landing site is now named the Hubert Curien Memorial Station, in recognition of one of the founders of ESA. The technical and scientific achievement of Huygens shows our capability to land on faraway worlds. It marks the beginning of the systematic exploration of outer solar system objects.

Future Directions

The lessons learnt from Huygens will be used in future to return to Titan and explore in details its surface in many locations. This was already envisaged with an international mission such as the Titan Saturn System Mission (TSSM). The TSSM, jointly studied by NASA and ESA,

planned to send a lander to explore one of Titan's lake and a Montgolfier to study for several months Titan's atmosphere and surface.

Hybridization

Carlos Briones
Centro de Astrobiología (CSIC/INTA), Consejo Superior de Investigaciones Científicas, Madrid, Spain

Definition

In ► [genetics](#), hybridization is the process by which two genetically unrelated parents –

belonging to different strains, varieties, ► [species](#), or even genera – are crossed or mated to originate a hybrid organism. For example, a mule is a hybrid animal produced by crossing a female horse with a male donkey, whereas the grapefruit is a hybrid between a sweet orange and a pomelo. In turn, in molecular biology, hybridization is the process by which two biomolecules or fragments of them interact specifically with each other. ► [Nucleic acid](#) hybridization is the process of annealing two single-stranded (ss) DNA or ssRNA molecules of different origin to form a double-stranded (ds) DNA, a dsRNA, or a DNA-RNA duplex. Both nucleic acid strands must bear some sequence similarity in order to form stable hybrids by complementary base pairing. The process can be induced in the test tube or, alternatively, used for detection and identification of complementary sequences in ex vivo samples. Different hybridization techniques have been implemented in molecular biology and biotechnology, including membrane-based blot methods and microarray technology.

Hydantoin,
Fig. 1 Hydantoin

Definition

Hydantoin ($C_3H_4N_2O_2$) is an organic compound whose structure is shown in Fig. 1. It is a saturated heterocyclic molecule related to imidazole which contains two lactam, or cyclic amide, functions. From an astrobiological point of view, it could be important for two main reasons: (1) it is formed from condensation of ► [urea](#) and ► [glycolic acid](#), or cyanate and ► [glycine](#), likely common prebiotic molecules which have also been detected in two meteorites, including Murchison, and, more importantly, (2) it is a precursor in the formation of N-carbamoyl amino acid (NCA) or hydantoic acid, which may be an important intermediate in the formation of oligopeptides. More generally, hydantoins are cyclic molecules formed from N-carbamoyl-amino acids.

Keywords

Carbonaceous meteorites · Fatty acids ·
Fischer-Tropsch-type reactions · Interstellar
grains · Pyruvate · Ultraviolet photon

Definition

Hydrocarbons are organic compounds consisting entirely of carbon and hydrogen. They may be synthesized from primary carbon sources such as carbon monoxide. The major source of prebiotic hydrocarbons on Earth might have been carbonaceous meteoritic infalls. Prebiotic significance of hydrocarbons could be found in their derivatives including the carbonyl group.

Overview

A major source of hydrocarbons for prebiotic evolution on Earth may be extraterrestrial material. Hydrocarbon derivatives constitute several percent of the total mass of carbonaceous meteoritic infalls, in contrast to amino acids that are present only in trace amounts in carbonaceous meteorites. The meteoritic infalls are in the form of interstellar grains composed largely of silicate minerals coated by thin layers of ice and frozen gases of such as carbon dioxide, carbon monoxide, ammonia, and methanol as well as a variety of small organic compounds including hydrocarbons as a principal ingredient. The synthesis of hydrocarbon derivatives in the icy mantles of interstellar grains could be initiated by irradiation by ultraviolet photons from a remote star.

The hydrocarbon derivatives of meteoritic origin, once they were delivered to Earth, would mostly be buried in the ocean. A smaller fraction would eventually be released into the periphery regions of hydrothermal environments and not necessarily right in the vicinity of black smokers, which are full of sulfur-containing chemicals. Insofar as small hydrocarbon derivatives such as formic acid or oxalic acid or their precursors are available in the periphery of hydrothermal environments at temperatures even less than 200 °C, Fischer-Tropsch-type reactions with the aid of metallic catalysts can work without being disturbed by the destructive interference from sulfur (McCollom et al. 1999). If the reaction solution is maintained at appropriately high pressures and temperatures, elongation of the alkyl chain can occur. A consequence is the synthesis of saturated

fatty acids such as decanoic acid. Once fatty acids are synthesized in aqueous environments where ionic strength is not sufficiently high, fatty acid vesicles are likely to be formed because of their amphiphilic nature. The presence of the vesicles can provide a means of encapsulating smaller monomers, enhancing the likelihood of further synthetic reactions to proceed in the vesicles.

Hydrocarbon derivatives have also been synthesized from pyruvate in prebiotic evolution experiments. Pyruvate itself has been synthesized from carbon monoxide using iron sulfide working as a reducing agent at 250 °C in experiments simulating black smokers (Cody et al. 2000).

Hydrodynamic Escape

Francis Albarède

Laboratoire de Géologie de Lyon, Ecole Normale Supérieure de Lyon, Lyon Cedex 7, France

Definition

The term *hydrodynamic escape* refers to the removal of gas from the atmosphere of a planet possessing a strong gravity field by the viscous drag of an escaping lighter gas, typically hydrogen. This phenomenon may explain why some planetary atmospheres are depleted in oxygen, nitrogen, and heavier noble gases, such as xenon.

Overview

When atmospheric temperature is high enough, the thermal agitation of gas molecules may be strong enough for some gaseous species to leave the gravity field of the planet. For a planetary body with radius R_p , Jean's escape velocity is obtained by equating the kinetic and potential energy and is equal to $\sqrt{2GM/R_p}$, with G being the universal gravitational constant and M the mass of the planet. For the Earth, escape velocity is 11.2 km s⁻¹. The mean thermal (translational) velocity of atoms in a gas is $\sqrt{8RT/\pi m}$, where m is the atomic mass of the gas and R is the gas constant (8.314×10^{-3} amu (km/s⁻¹)). For monatomic hydrogen, $m = 1$ g/mol⁻¹ and the thermal velocity is 2.5 km s⁻¹ at ambient temperature (298 K). Although this value is less than the escape velocity, a tiny fraction of hydrogen leaves the upper terrestrial atmosphere. In contrast, the thermal velocity of monatomic nitrogen is 700 m s⁻¹, and nitrogen remains in the atmosphere.

For a dense atmosphere, gas molecules collide with each other very frequently, and the distance between successive collisions (mean free path) is short. Let us imagine traces of monatomic nitrogen in an atmosphere of monatomic hydrogen. Collision with hydrogen, which on average tends to expand and leave the gravity field, imparts momentum to nitrogen atoms. Although thermal agitation would not be sufficient to remove this species from an atmosphere of pure nitrogen, the hydrogen viscous drag adds extra velocity to other species and may remove them to space. Hydrogen loss from early planetary atmosphere results in the loss of other species. This phenomenon, which is known as hydrodynamic escape, was elucidated by Hunten et al. (1987). There are some suggestions that Mars and Venus may have lost nitrogen and water in this way (e.g., Pepin 1991).

Hydrodynamic Flow

Steven B. Charnley

Solar System Exploration Division, Code 691, Astrochemistry Laboratory, NASA Goddard Space Flight Center, Greenbelt, MD, USA

Definition

The term hydrodynamic flow describes a dynamical approximation for the bulk motion of matter in which it is treated as a fluid (gas or liquid), rather than as a collection of particles.

Hydrogen

Henderson James Cleaves II

Earth-Life Science Institute (ELSI), Tokyo Institute of Technology, Tokyo, Japan
Blue Marble Space Institute of Science, Washington, DC, USA
Georgia Institute of Technology, Center for Chemical Evolution, Atlanta, GA, USA

Definition

Hydrogen (chemical symbol H) is a chemical element with atomic number 1. It has an atomic weight of 1.00794 u (or Da) (1.007825 u for the isotope ^1H containing no neutrons). It is the lightest and most abundant element, making up ~75% of the Universe's detectable mass and ~90% of its detectable atoms.

Main sequence stars are mostly composed of ionized hydrogen in plasmas, which play a vital role in powering stars through proton-proton

reactions and the CNO nuclear fusion cycle. Hydrogen has three naturally occurring isotopes: ^1H , ^2H , and ^3H , which all contain 1 proton and 0, 1, or 2 neutrons, respectively. While hydrogen gas is rare in the Earth's atmosphere (~1 ppm by volume) because it escapes from the Earth's gravity field more easily than heavier gases, it is the third most abundant element on the Earth's surface, mainly as a component of water.

Its most common isotope is ^1H (protium), which contains a single proton. In ionic compounds, hydrogen can take a negative charge (forming an anion known as hydride and written as H^-), or as a positively charged species H^+ , also known as a proton. Hydrogen forms molecular compounds with most elements. It plays an important role in Bronsted-Lowry acid-base chemistry with many reactions exchanging protons between soluble molecules.

Molecular hydrogen (H_2), which is a gas at room temperature and pressure, was first produced artificially in the sixteenth century by Paracelsus by mixing metals with strong acids. In 1766–1781, Cavendish was the first to recognize hydrogen gas as a discrete substance, and that it produces water when burned in air. This property led to it receiving its name, which is from the Greek meaning “water-former.” Molecular hydrogen is highly inflammable and burns readily in air:

The energy levels of hydrogen can be calculated fairly accurately using the Bohr model of the atom. However, a more accurate description of the hydrogen atom comes from a purely quantum mechanical treatment that uses the Schrödinger equation, which allows the calculation of the probability of the electron density around the proton.

Protonated molecular hydrogen, or H_3^+ , is found in the interstellar medium, where it is generated by ionization of molecular hydrogen by cosmic rays. H_3^+ is relatively stable in outer space due to the low temperature and matter density. H_3^+ is thus one of the most abundant ions in the universe, and plays an important role in the chemistry of the interstellar medium.

Hydrogen in the ► [interstellar medium](#) can exist as neutral atomic hydrogen (referred to by

astronomers as HI), as ionized atomic hydrogen (protons, called HII), or as molecular hydrogen (H₂). Atomic hydrogen is typically observed by its hyperfine transition at a wavelength of 21 cm, accurately predicted by Dutch graduate student Hendrik van de Hulst in 1944. Regions of ionized hydrogen, produced by ultraviolet radiation from hot stars, are detected from recombination lines such as those in the Balmer series. Molecular hydrogen has no transitions in the visible portion of the spectrum, and was first observed by G. Carruthers in the ultraviolet, using a rocket-borne spectrograph.

Hydrogen forms millions of known molecular compounds with other elements, in particular carbon. Hydrogen forms molecular compounds with elements that are more electronegative than it is, such as the halogens. In these compounds, hydrogen has a partial positive charge. Hydrogen also forms molecular compounds with less electronegative elements, such as the metals and metalloids, in which case it takes on a partial negative charge. These compounds are called hydrides.

Large quantities of hydrogen gas are produced by reaction of water with mantle minerals (such as olivine), notably on the sea floor. It is widely believed that this process, called serpentinization, may have created a reduced environment favorable for the origin of life.

Hydrogen Bond

Gilles Bruylants
Engineering of Molecular NanoSystems,
Universt  Libre de Bruxelles, Brussels, Belgium

Keywords

Molecular interactions · Noncovalent interactions

Synonyms

[H bond](#)

Overview

A hydrogen bond (H bond) is the attractive non-covalent interaction between a hydrogen atom covalently bonded to an electronegative atom (hydrogen bond donor) and another electronegative atom (hydrogen bond acceptor), such as nitrogen, oxygen, or fluorine.

The hydrogen bond has some features of covalent bonding: it is directional, produces interatomic distances shorter than the sum of the van der Waals radii, and usually involves a limited number of interacting partners, which can be interpreted as a type of valence. These covalent features are more substantial when the hydrogen atom is bonded to a more electronegative atom. The hydrogen bond is relatively strong (usually between 5 and 30 kJ/mol but extremely strong values such as 155 kJ/mol in the HF₂[−] molecule are observed, in which case the term Low Barrier Hydrogen Bond is frequently used) compared to other non-covalent interactions, such as van der Waals interactions, but weaker than covalent or ionic bonds. The bond strength depends on its length, the bond angle, the local dielectric constant, the electronegativity of the non-hydrogen atoms, temperature, and pressure.

Hydrogen bonds can occur between molecules (intermolecular hydrogen bond) or within different parts of a single molecule (intramolecular hydrogen bond).

The most ubiquitous example of an intermolecular hydrogen bond is the one found between water molecules. The water molecule is composed of two hydrogen atoms which can form a hydrogen bond (as donors) and one oxygen atom which has two lone pairs of electrons, each of which can be involved in a hydrogen bond (as acceptors). In liquid water, every water molecule can consequently be hydrogen bonded with up to four other molecules.

Hydrogen bonding also plays an important role in determining the three-dimensional structure adopted by larger molecules including macromolecules such as ▶ [proteins](#) and ▶ [nucleic acids](#). The double helical structure of DNA is due largely to

hydrogen bonding between the ► [base pairs](#), which link one complementary strand to the other. In proteins, hydrogen bonds between the backbone oxygen atoms and amide hydrogen atoms contribute to the formation of secondary structure elements, such as alpha helices and beta sheets. In addition, many proteins have hydrogen bonds between side chains. Taken together, these interactions contribute to folding proteins into specific shapes that determine their biological function. However, the importance of this contribution to stability of the folded state still remains controversial, as both donors and acceptors of hydrogen bonds can form hydrogen bonds with water when unfolded in aqueous solution.

Hydrogen Chloride (HCl)

William M. Irvine
Department of Astronomy, University of
Massachusetts, Amherst, MA, USA

Synonyms

[HCl](#)

Definition

Hydrogen chloride is a colorless gas under standard conditions, consisting of diatomic molecules containing hydrogen and chlorine. Two isotopologues have been detected by astronomers.

History

Interstellar HCl was first detected in 1985 from the Kuiper Airborne Observatory by G. Blake and colleagues (Blake et al. [1985](#)). Although it is detected in the gas phase in interstellar molecular clouds (Schilke et al. [1995](#)), the majority of the chlorine in these regions appears to be sequestered in the ► [interstellar dust](#) grains (Cernicharo et al. [2010a](#)). The two isotopic species, H^{35}Cl and H^{37}Cl , have been detected with the Herschel satellite toward evolved stars (Cernicharo et al. [2010b, c](#)). More recently, the cations HCl^+ and H_2Cl^+ have also been detected in molecular clouds (e.g., De Luca et al. [2012](#); Neufeld et al. [2012](#)). HCl has also been detected in Comet 67P/Churyumov-Gerasimenko (De Keyser et al. [2017](#)).

Hydrogen Cyanamide

► [Cyanamide](#)

Hydrogen Cyanide

José Cernicharo Quintanilla
Laboratory of Molecular Astrophysics,
IFF-CSIC, Madrid, Spain

Synonyms

[Formonitrile](#)

Definition

Due to its dual reactivity, as both a nucleophile and an electrophile, hydrogen cyanide, HCN, plays an important role in many synthetic processes potentially related to the origin of life. At room temperature, it is a colorless and extremely poisonous gas, with a bitter odor reminiscent of almonds that some people are unable to perceive for genetic reasons. It has been found in molecular clouds (Snyder and Buhl 1971), evolved stars (Wilson et al. 1973), and comets (Huebner et al. 1974; Despois et al. 1986). It is one of the most abundant triatomic species in

space. Its less stable isomer ► [hydrogen isocyanide](#), HNC, has also been found in space (Snyder and Buhl 1971; Saykally et al. 1976). In molecular clouds, both isomers form from the dissociative electronic recombination of HCNH^+ . In cold molecular clouds, the abundance ratio HCN/HNC is of order unity (Sarrasin et al. 2010). HCN plays an important role in chemical reactions thought to have been important on the primitive Earth, for example, in Miller-Urey-type experiments (via its involvement in the Strecker amino acid synthesis) and in its self-condensation reactions that produce both amino acids and nucleic acid bases (Oró 1961).

Hydrogen Cyanide Polymer

► [HCN Polymer](#)

Hydrogen Ion Concentration Index

► [pH](#)

Hydrogen Isocyanide (HNC)

William M. Irvine
Department of Astronomy, University of
Massachusetts, Amherst, MA, USA

Synonyms

[HNC](#)

Definition

Hydrogen isocyanide (HNC) is a linear triatomic molecule that is an isomer of HCN, hydrogen cyanide, the latter being a key intermediary in several possible pathways for the production of important biological molecules. HNC itself is one of the more abundant triatomic molecular species in interstellar clouds, where the abundance ratio HNC/HCN appears to be sensitive to temperature. Because of its relatively large electric dipole moment (and hence rapid transitions to lower energy states) and since higher energy levels are populated by collisions with molecular hydrogen (the most abundant cloud species), the intensity of HNC rotational transitions can be used to estimate density in molecular clouds. Hydrogen isocyanide is also observed in cometary comae.

History

Hydrogen isocyanide was initially detected in the interstellar medium in 1971 by L. Snyder and D. Buhl. Because HNC is considerably higher in energy than its isomer HCN, at thermal equilibrium its abundance in the interstellar medium

would be essentially zero. Instead, in cold clouds, its abundance can equal or even exceed that of HCN. This evidence for the kinetic control of isomerization pathways was one of the strongest early observational supports for ion-molecule models of interstellar chemistry (Herbst 1987). Hydrogen isocyanide was first observed in a comet in Comet Hyakutake in 1996, but there is evidence that it may be primarily produced in the coma rather than being a constituent of the icy nucleus (Irvine et al. 1998; Cordiner et al. 2017)

Chemical Formula

H_2S

Definition

Hydrogen sulfide is a colorless and poisonous gas with a strong odor of rotten eggs and the chemical formula H_2S . It occurs in volcanic gases and natural gases. It is produced by breakdown of organic matter, as a product of microbial sulfate reduction (when bacteria use sulfate as the terminal electron acceptor during growth under anoxic conditions), and by liberation from sulfide minerals. Being abundant in the prebiotic Earth, the H_2S figures out in many “[origin of life](#)” models (e.g., Olson and Straub 2015), especially those positing an origin near black smoker-type hydrothermal vents. It is found both in interstellar molecular clouds and in comets. The sulfanyl radical, SH, and

the corresponding cation sulfaniumylidene (sulfanylium), SH^+ , have also recently been detected in the interstellar medium.

Definition

In chemistry, hydrolysis refers to a chemical reaction in which molecules are split by the addition of a molecule of water. One fragment of the parent molecule gains a hydrogen ion (H^+), while the other group receives a hydroxyl group (OH^-).

Hydrolytic reactions catalyzed by both acid and base are common, for example, the hydrolysis of ► [amides](#) or esters. Their hydrolysis occurs when a nucleophile (water or a hydroxyl anion) attacks the ► [carbonyl](#) group of the ester or amide. In water, hydroxyl ions are better nucleophiles than water itself. In acid, the carbonyl group becomes protonated, and this leads to easier nucleophilic attack. The products of the hydrolysis of amides and esters are a carboxylic acid and an amine, and a carboxylic acid and an alcohol, respectively.

Under physiological conditions, in which the concentrations of a hydrolysable reactant and its products are low (on the order of 10^{-3} – 10^{-6} molar), the hydrolysis reaction, such as the hydrolysis of a peptide to amino acids, is essentially thermodynamically irreversible. For example:

Here the ΔG for the reaction is ~ -3.5 kcal/mole, and the spontaneous reassembly of amino acids to ► [peptides](#) is negligible.

Hydrophobic Effect

Lawrence Pratt
Tulane University, New Orleans, LA, USA

Keywords

Hydrophobicity · Hydrophobic interactions · Hydrophobic bonds

Definition

Hydrophobic effects are phenomena of aqueous solutions involving hydrophobic species or molecular groups, which are recognized by contrast to hydrophilic species or groups. Hydrophilic species typically have simply recognized chemical interactions with water molecules, e.g., ammonia (NH_3) or perhaps have electrostatic interactions with water, e.g., ions such as Na^+ . Hydrophilic species typically have substantial solubility in liquid water. In contrast, hydrophobic species, e.g., methane (CH_4) or hydrocarbons broadly, have less favorable interactions with water molecules, and predominantly interactions of van der Waals type. Hydrophobic species typically have low solubilities in water. Hydrophobic groups can be combined with hydrophilic groups

in larger molecules, and this vastly extends the functionality of molecules like that. Molecules that combine hydrophobic and hydrophilic groups are called amphiphilic. Sodium dodecylsulfate ($\text{CH}_3(\text{CH}_2)_{11}\text{OSO}_3\text{Na}$), a simple surfactant, is an example. The characteristic functionality of amphiphilic molecules is to coat aqueous solution interfaces, satisfying the tendency of hydrophilic groups for contact with water while also satisfying the tendency of hydrophobic groups to avoid contact with water. In fact, the appellation “surfactant” indicates that behavior.

The extended functionality of amphiphilic species can lead to self-assembled possibilities for organization of larger solution structures, including micelles, bilayer membranes, and specifically structured macromolecules such as folded water-soluble protein molecules. The balance of hydrophobic and hydrophilic effects can make the solution thermodynamic characterization of these solutions tricky. Since hydrophilic effects are typically more simply recognized and modeled, hydrophobic effects are associated with the additional complications exhibited by amphiphilic species. Those complications are typically unfavorable entropy change for dissolution, and

substantial temperature dependences for those entropy changes. Figure 1 gives examples of distinctions between solubilities of simple gases in water and cyclohexane, and distinctions in T -dependences. Distinctive T -dependences are often required for identification of hydrophobic effects for specific study.

History

Tanford's (1997) expansive discussion (Further Reading) gives an entertaining history of the genesis of the concepts and names associated with hydrophobic effects in the context of understanding soluble proteins. That historical discussion culminates with the watershed review article of Kauzmann (1959) (Further Reading), which marks an opening of the modern era in study of hydrophobic effects. Since the mid-1970s, analysis of the underlying molecular description of hydrophobic effects has extensively exploited the development of molecular-scale simulation with rapidly advancing computational tools. Ashbaugh and Pratt (2006) presented a modern perspective on the interplay between computer

Hydrophobic Effect, Fig. 1 Ostwald coefficient L for some simple gases in water (circles) and cyclohexane (stars). The Ostwald coefficient is the fractional amount of the gas in the solution relative to the amount in a coexisting dilute vapor phase. Thus $L = 0.05$ for O_2 at the lower temperatures here means that the concentration

of O_2 in the water is 5% of the concentration of O_2 in coexisting vapor. All results are for low (Earth) ambient pressures. Notice that this plot utilizes a logarithmic vertical axis. These gases are less soluble in water than in cyclohexane, and the T dependences display opposite trends. (Redrawn after Ashbaugh and Pratt 2006)

simulation work, molecular theory, and classic physical chemistry. A broader range of applications is considered in the review of Pratt and Pohorille (2002).

Overview

A striking feature of observed biophysical structures is that spatial organization is achieved by competing interactions, hydrophilic and hydrophobic interactions. The most primitive conceptualization of hydrophobic effects is just that water and oil can demix. Those phase equilibria, together with molecular-scale hydrophobic-hydrophilic amphiphilicity, can then result in spatially segregated mesoscopic structures (Further Reading: Tanford 1978). The driving force for oil-water phase separation is customarily viewed as a sticky interaction operating between hydrophobic species, but not as specifically as suggested by the old-fashioned term “hydrophobic bond”.

Phase separation is not the only interesting aspect of hydrophobic effects. Standard solution thermodynamic studies establish that the suggested hydrophobic stickiness becomes stronger as the temperature increases through a physiological range. This is experimentally clear in the phenomenon of cold-denaturation of proteins wherein cool, unfolded soluble proteins fold upon heating. That protein globules become more highly ordered with increasing T may seem counter-intuitive. But if the contacting aqueous solution becomes sufficiently disordered with T -increase, expectations from ordinary thermodynamics are restored. This suggests that the refolding of a cold-denatured protein is driven by the participation of the solution. Participation of the solution in stabilizing functional biomolecular structures is an aspect of hydrophobic effects.

Molecular theories and explanations of hydrophobic effects range from appeal to and parameterization of simple intuition to aggressive statistical mechanical theory of

solutions. Because these are problems of acknowledged importance and sometimes challenging to molecular-scale intuition, agreement on molecular theories and mechanisms has been imperfect. Ashbaugh and Pratt (2006) give a glimpse of the range molecular theories advanced for these phenomena.

An important aspect to hydrophobic effects is that the solvent water itself behaves unlike common organic solvents. Liquid water is typically a chemically active medium. It is stable over comparatively wide temperature range, and exhibits a large heat capacity that helps to moderate temperature excursions for the terrestrial biosphere. The Pohorille and Pratt (2012) discussion considered thermodynamic characteristics of solvents that might be compared to water. That survey identified non-water liquids glycerol, diethylene glycol, ethylene glycol, formamide, 2-aminoethanol, 1–4 butanediol, and 1–5 pentanediol, and mixtures of such solvents, as cases worthy of further study for comparison with liquid water in supporting a solvophobic/solvophilic dichotomy and perhaps leading to interesting self-assembly of functional larger-scale solution structures.

Hydrophobicity

Kensei Kobayashi
Yokohama National University, Yokohama, Japan

Definition

Hydrophobicity refers to the property of a molecule to resist dissolution in water. Organic compounds with ionizable or polarizable groups tend to be hydrophilic, as opposed to hydrophobic, as those groups may be favorably solvated by polar water molecules via hydrogen bonds and other mechanisms. On the other hand, organic compounds without polarizable groups are generally hydrophobic and thus show low solubility in water. Alkanes are typical hydrophobic molecules. When hydrophobic molecules are placed in water, water tends to exclude them. This is called the hydrophobic effect. Molecules with both hydrophilic groups and hydrophobic groups are called amphiphilic molecules. Hydrophobicity and amphiphilicity are important in the self-assembly of organic molecules which may have been important in the origin of biological membranes.

Amino acids show a variety of hydrophobicities due to their variable side chains. Phenylalanine and leucine have large hydrocarbon groups and show high hydrophobicity, while aspartic acid and lysine show low hydrophobicity (high hydrophilicity) due to ionizable groups in their side chains. Various hydrophobic scales are sometimes used to evaluate the hydrophobicity of amino acids and other compounds.

Hydrosphere

Nicholas Arndt
Emeritus Professor, ISTerre, University Grenoble Alpes, Grenoble, France

Definition

The *hydrosphere* is the combined mass of water in the atmosphere, at the surface, and in the interior of the Earth and of other planetary bodies. About 97% of the total volume of the Earth's hydrosphere ($1.335 \times 10^9 \text{ km}^3$) is in the oceans; the remaining $\sim 3\%$ is in the continental ice caps ($\sim 1.7\%$), groundwater ($\sim 1.3\%$), lakes and rivers ($\sim 0.013\%$), and the atmosphere ($\sim 0.0009\%$). Up to five times the surface volume of the oceans may be present in the mantle, fixed in the structure of nominally anhydrous minerals. Mars appears to have had a small liquid hydrosphere early in its history and retains water in ice caps and in the subsurface. A thick hydrosphere covers the Jovian moons Europa (ca. $3.8 \times 10^9 \text{ km}^3$) and perhaps Ganymede and the Saturnian moon Enceladus.

Hydrostatic Balance

- [Hydrostatic Equilibrium](#)

Hydrostatic Equilibrium

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Synonyms

[Hydrostatic balance](#)

Definition

Hydrostatic equilibrium designates a stable state of a fluid where there is a condition of balance between gravitational force and pressure gradient. In a planetary atmosphere, under simplifying assumptions (perfect gas, isothermal), the hydrostatic equilibrium condition leads to a law of pressure (p) variation with altitude (z) that is exponential: $p = p_0 \exp(-z/z_0)$, where z_0 is the scale height (8 km on Earth). In a star, the radiation pressure creates an additional outward force that participates in the hydrostatic equilibrium equation. Note that hydrostatic equilibrium implies that the star's or planet's shape is a sphere in the simplest case and an oblate spheroid for a rotating body.

Definition

Hydrothermal alteration is defined as any change in the mineralogic composition of a rock due to the action (by either physical or chemical means) of hydrothermal fluids in an open system.

History

Hydrothermal alteration has been recognized on Earth since the onset of geology. It is a very common process, and it is often associated with mineral deposits. Hydrothermal alteration was suspected on Mars from observations carried out by early ► [Viking](#) landers (Newton and Hagerty 1997), and it was discovered on the ground by the Mars Science Laboratory rover "Curiosity."

Overview

Hydrothermal alteration marks the disequilibrium between fluids, usually aqueous, and rocks, usually silicate-rich. Hydrothermal alteration has been observed on Mars and is presumed to exist on other small ocean planets (Pirajno 2009). Smaller planets show rock porosity to a greater depth than the Earth, allowing deeper hydrothermal fluid circulation and exchange to exist.

On ► [Mars](#), alteration mineralogy can be determined from the composition of impact craters, which provide natural probes into the subsurface. Alteration minerals occur as large unsaturated, partially altered zone, without contact with the atmosphere. Mud volcanoes reflect the importance of such clay formation at depth. Two styles of alteration have been recorded: low-pH alteration, marked by sulfate deposits, and neutral to high-pH alteration, marked by crystallization of chlorite, nontronite, saponite, serpentine, and carbonates. Such alteration could be produced by hydrothermal systems related to impacts, high-temperature geothermal systems related to plume

volcanism (Tharsis), and zones of high geothermal gradient (Ehlmann et al. 2011). Impact activity induced localized hydrothermal system near the borders of the craters, and such activity may last several million years after the impact. The subsurface alteration peaked in the early stage of Mars' evolution, in the Noachian (>4.1 Gyr ago) and into the Early Hesperian (3.7–4.1 Gyr ago). Serpentine is uncommon but has been found in *mélange* terrains, impact craters, and within a regional olivine unit near the Isidis basin.

In other small ocean planets (► [Titan](#), ► [Ganymede](#), ► [Callisto](#), ► [Europa](#), ► [Enceladus](#)), hydrothermal alteration is assumed due to the probable onset of hydrothermal systems and the formation of liquid water at the contact within the cryosphere (Vance et al. 2007).

Zones of hydrothermal alteration may impact the topography by facilitating collapse of hydrothermal zones. Increase of porosity, higher temperature, and presence of water in hydrated minerals may have facilitated the establishment of subsurface biota. Carbon monoxide-bearing fluids infiltrated from the surface could have reacted with the hydrogen from serpentinization to form methane, which could have fuelled ► [methanotrophs](#) and been mediated by ► [methanogens](#) (Michalski et al. 2013). Alteration of basaltic rocks releases Fe and Mg cations which can fuel iron respiration and facilitate the formation of complex organic molecules.

Hydrothermal Environments

Nicholas Arndt

Emeritus Professor, ISTerre, University Grenoble Alpes, Grenoble, France

Keywords

Black smoker · White smoker · Hydrothermal fluid · Oceanic crust · Origin of life · Serpentinization

Definition

A *hydrothermal environment* is a setting dominated by the circulation of hot, mainly aqueous fluids. In a mid-ocean ridge setting, seawater penetrates the oceanic crust, becomes heated, interacts with the oceanic crust so that its chemical composition changes, and then exits at a hydrothermal vent (black and/or white smoker) on the ocean floor. The environment surrounding the vent sustains rich, anoxic chemotrophic ecology. This environment is a possible setting for the emergence of life on Earth.

Overview

The simple definition of a hydrothermal fluid is a hot water-rich fluid in the Earth's crust. The origin of the fluid is diverse, ranging from seawater that penetrates down into the oceanic crust or fills pore space in sedimentary basins to magmatic fluid released from crystallizing igneous intrusions. These fluids are heated as they descend into the oceanic and/or continental crust or encounter magmas. Hot fluids can transport large volume of materials derived from the parent magma or leached from surrounding rocks, and many of the world's greatest ore deposits form as metals such as Cu, Zn, Au, or U precipitate from hydrothermal fluids.

In astrobiology, the most important hydrothermal environment is close to the surface of the oceanic crust, at or near a mid-ocean ridge. As

seawater penetrates the oceanic crust, it becomes heated and interacts with the crust so that its chemical composition changes (Humphris et al. 1995; Alt and Teagle 2000; Früh-Green et al. 2007). It then may exit at a hydrothermal vent on the ocean floor. Components leached from basaltic rocks of the crust – sulfide or sulfate, silica, oxides, and carbonates – precipitate as the fluid is cooled and becomes diluted as it mixes with seawater. These components are initially dispersed in the plume that ascends from the vent, or they flocculate around the vent to form chimneys (black and white smokers) whose height might reach 60 m. Particles raining out from the plume produce a layer of sediment, to which the relicts of chimneys (which topple when they become too tall and unstable) are added. The product is a lens of “exhalative” sulfide, which, if accreted to the continent, can be mined for metals such as Cu, Zn, and Pb (Tivey 2007).

Fluids that circulate at a mid-ocean ridge become strongly heated and acidic as they interact with basaltic crustal rock. Such fluids dissolve large quantities of Fe-Cu-Zn sulfides that precipitate as small particles within the fluid as it exits the vent, imparting a black color to the hydrothermal plume and giving rise to the term “black smoker.” Such fluids interact with very hot rock adjacent to magma chambers beneath the ocean ridge; their temperatures may reach 400 °C. In environments off the mid-ocean ridge axis, reactions between seawater and ultramafic rocks (through process called serpentinization) produce methane- and hydrogen-rich fluids that are highly alkaline, with lower temperatures ranging from about 40 °C to 90 °C. These fluids are rich in dissolved carbonate and sulfate; when they exit from the ocean floor, they form “white smokers.”

The areas around hydrothermal vents often host complex communities of archaea, bacteria, and larger, more diverse organisms, including giant tubeworms, clams, limpets, and shrimps. These deep-sea organisms have no access to sunlight and depend on the hydrothermal fluids for nutrients and energy. The archaea and bacteria use sulfur compounds, particularly hydrogen sulfide, to produce organic matter via chemosynthesis. The bacteria surround the hydrothermal vent

area with a thick mat that attracts other organisms such as amphipods and copepods that graze on the bacteria. Larger animals complete the food chain. The main families found around seafloor vents are annelids, pogonophorans (marine wormlike animals), gastropods, bivalves, and crustaceans, together with the famous tubeworms that epitomize the vent community.

Corliss et al. (1981) and Wächtershäuser (1990), a German chemist turned patent lawyer, suggested that life might have originated at hydrothermal vents early in the Archean. It is well established that organic compounds are produced by inorganic, ► **Fischer-Tropsch-type** reactions deep in the oceanic crust when hot aqueous fluids react with minerals like olivine or pyroxene. These compounds were transported in hydrothermal fluids to the seafloor where they interacted with seawater. The presence of clay minerals provided templates that foster the formation of peptides and protocells. Martin and Russell (2007) proposed that as hydrothermal fluid emerged at the ocean floor, it reacted inside small metal sulfide cavities within hydrothermal vent chimneys. Large chemical and thermal gradients between the interior and exterior of the chimney provided the microenvironment for life-forming chemical reactions to take place.

Active hydrothermal vents may exist on Jupiter’s moon Europa, and alteration minerals that might have resulted from the circulation of hydrothermal fluids have been found on Mars.

Basic Methodology

Active hydrothermal vent systems are observed from submersibles – small submarines that can descend to the great depths of the ocean floor. Scientists record the activity of the vents, register the flux and the physical characteristics of the fluids, and take samples of the fluids, of the chimneys, and of surrounding sedimentary deposits and eventually organisms. These are analyzed in the laboratory – the fluids for their composition and other characteristics (acidity and oxidation state), the rock samples for their mineralogy, and geochemical composition. Several vents have

been sampled by scientific drilling as part of the Integrated Oceanic Drilling Program (IODP). Fossil hydrothermal vents are studied in sections that have been obducted onto, or accreted to, the continental crust. Notable examples are in Cyprus and in mining areas such as the Abitibi greenstone belt in Canada and the Urals.

Key Research Findings

Hydrothermal circulation plays an important role in cooling the oceanic crust; hydration of basalts strongly affects its composition; and release of fluids in subduction zones controls island arc magmatism and contributes directly to the growth of continental crust. Hydrothermal fluids form accumulations of Cu, Zn, and Pb sulfides, which are mined when the deposits are found on the continents. Unusual bacterial and animal communities surround active hydrothermal events. Hydrothermal vents in the early Archean may have been the site of the emergence and early evolution of life.

Future Directions

Investigation of hydrothermal vents is continuing as part of the Integrated Ocean Drilling Program and other oceanographic programs. The biological community is involved through their research on the ecology of hydrothermal vents. The search for a better understanding of the reactions that produced prebiotic compounds continues. Companies and government organizations are investigating how active submarine hydrothermal systems might be mined as a source of metals such as Cu, Zn, and Au.

Exergonic reactions · Heating · Hot vents · Hydrolysis · Hydrothermal circulation · Quenching · Selective retention

Definition

Hydrothermal reactions are chemical reactions that take place in or near hydrothermal vents. Of importance from the perspective of prebiotic chemistry is the fact that the two processes, heating and quenching, are separated due to the repeated hydrothermal circulation of seawater around the hot vents. Heating is indispensable for activating the reactants for a wide variety of synthetic reactions, while quenching is crucial for selectively retaining some of those species that are synthesized. Heating and quenching experienced sequentially during hydrothermal circulation of seawater can make prebiotic chemistry evolutionary without being entrapped in thermal equilibrium in which both heating and quenching remain inseparable.

Overview

Hydrothermal reactions are classified into two distinct groups. One is for the reactions in thermal equilibrium, and the other is for those off thermal equilibrium.

Experimental examination of synthetic chemical reactions in thermal equilibrium starts from the reactants supplied externally to an environment initially prepared in thermal equilibrium and specifies the character of the final synthetic products precipitated under the imposed equilibrium conditions. An advantage of hydrothermal reactions examined under the present methodology is in the appraisal of exergonic reactions at higher temperatures compared to endergonic ones expected at lower temperatures, though it may look counterintuitive at first sight. A case in point is an estimate of the thermodynamic likelihood of synthesizing amino acids from their precursors in moderately reducing hydrothermal environments. Thermodynamic evaluation in terms of the Gibbs free energy reveals that the synthesis of many amino acids is exergonic when synthesized from their component smaller molecules at temperature 100 °C, whereas the synthesis is endergonic at 18 °C (Amend and Shock 1998).

That synthesizing organic molecules such as amino acids in hydrothermal environments is exergonic implies the synthetic reactions be energetically downhill and is quite welcome from the perspective of prebiotic synthesis at least until finally reaching thermal equilibrium. Evolutionary relevance of chemical reactions in thermal equilibrium is thus sought in how the initial reactants could be prepared and how the reaction products could be removed. In fact, equilibrium prebiotic chemistry can provide a wide variety of reaction products depending upon the choice of the initial reactants. Some products might indeed catalyze reactions that have some prebiotic utility, but other products may well inhibit such catalysis or catalyze adverse reactions. An example of this sort is seen in the clay-catalyzed condensation of nucleotides, which could work best if only one type of enantiomer of the starting material is present, while if both types were present, catalytic condensation of one enantiomer could be disturbed and inhibited by the presence of the other enantiomer (Joyce and Orgel 1999).

Instrumental to making prebiotic chemistry evolutionary must therefore be naturalization of the coordination of both supplying the initial reactants to and removing the products from reaction sites in an integrated manner. One natural candidate for meeting this challenge is constant circulation of seawater through the periphery or the vicinity of hydrothermal vents, the latter of which could work as reaction sites because of the availability of heat energy for activating various reactions. Both reactants and products are carried by the circulating flow of seawater and visit the hot reaction sites occasionally, while the flow stays in the vast cold ocean during most of the time. Chemical reactions proceeding within the circulating flow are undoubtedly not in thermal equilibrium due to crossing the temperature gradients generated around the vents repeatedly as dismissing the occurrence of stationary chemical reactions anchored at thermal equilibrium.

When one tries to figure out the average frequency of an arbitrary tiny droplet of seawater in the ocean visiting one hydrothermal ridge system, its modest estimate would give about once every 30 million years upon the conjecture that the

weight of the total seawater on the surface of Earth is of the order of 10^{18} t and the water issued from a single ridge system is about 1000 t per second. If there are about 1000 independent hydrothermal ridge systems in the ocean even prior to the emergence of the major continents, the frequency of a tiny droplet visiting any one of the ridge systems could be raised to about once every 30 thousand years. This numerical exercise simply gives a possible lower limit to the actual visiting frequency. The actual visiting can however be made far more frequent locally because of the participation of a wide variety of shortcuts.

Geology-assisted hydrothermal circulation of seawater is peculiar in converting the preceding reaction products in the solution into the succeeding reactants when visiting hot spots again and again, after being subject to rapid quenching every time. This hydrothermal conversion from products to reactants can have a natural tendency to enhance the synthesis of products of a specific kind. The underlying chemistry is pretty simple. Suppose one starts with a solution of monomers of a single kind to be circulated. Elongation of oligomers out of the initial monomers could be expected when both precursor oligomers and monomers are visiting hot spots, while those products that could be hydrolyzed back into the original monomers are released into the cold surroundings. Only those derivatives that could survive the preceding period of hydrolysis even partially may participate in the further elongation when they visit the hot spots the next time. The elongated products are thus inclined to selectively maintain only those oligomers of the kind that could be evolutionary in keeping the preceding memory of synthesis even partially.

There is nothing special with both thermal synthesis of products and their hydrolysis in prebiotic chemistry. However, if one conceives of both within the homogeneous scheme of chemical reactions in thermal equilibrium, a formidable obstacle would come up. No separation between synthesis and hydrolysis is possible there. Synthesis and hydrolysis would produce a homogenized mixture in thermal equilibrium, with ending up with a mere mixture of complex products and no chemical evolution.

What is specific to hydrothermal circulation of seawater around the hot vents in the ocean is its natural capacity of separating between synthetic production and selective retention of the products. As a matter of fact, one may be able to observe how products would be synthesized in the hot spots and how those products could subsequently survive their possible hydrolysis when transferred into the cold surroundings by following the streamline of the circulating fluid sequentially. What remains to be seen is to address the tractable issue of whether the present picture of separating synthetic production from selective retention of the products could experimentally be testable.

One relevant experiment is the synthesis of oligopeptides from monomeric glycine in a flow reactor simulating hydrothermal circulation of seawater in the ocean, while setting the frequency of visiting a hot spot (225 °C) to be once every 30–80 s instead of every 30,000 years (Imai et al. 1999). When the frequency of visiting the hot spot was raised from once every 78 s to every 34 s, the yields of oligomeric products were found to increase accordingly. The increase of the yields demonstrates the cumulative nature of synthetic production in the sense that the yields increased exponentially with the increase in the frequency of visiting the hot spot.

Unless the synthetic production and selective retention of the products are forcibly homogenized as in theoretical chemical reactions in thermal equilibrium, prebiotic chemistry proceeding in inhomogeneous thermodynamic conditions (such as those applied to hydrothermal circulation of seawater) could already be selective in retaining only a specific set of synthetic products. Unique to the selective retention of the products associated with the hydrothermal reactions is the built-in selective sieve for those products surviving rapid quenching that takes place soon after the products leave the hot spots and enter into the cold environments. In particular, there are at least two distinct fates waiting for the product entering into the cold. One is to lower the temperature of the product with the aid of its hydrolysis, and the other is to lower the temperature of the product by storing the acquired heat energy internally in the form of chemical bonds without suffering

hydrolysis. Which will win depends entirely upon which is faster. This is the situation of winner takes all. Those that could not survive rapid quenching would necessarily be pruned off.

Prebiotic chemistry aimed at addressing the origins of life has to face two different tasks in an integrated manner at the same time. One task is to prepare the chemistry that could be sufficiently synthetic and versatile enough to be amenable to evolutionary adaptation. And another one is to secure the chemistry that could be sufficiently fine tuned and specific enough to maintain a well-orchestrated self-organization. At first sight, these two tasks would seem contradictory. Despite that, chemical reactions riding on hydrothermal circulation of seawater may suggest to us a loop-hole for reaching out to a meaningful integration of the seemingly contradictory tasks by letting the circulating flow serve as a unifying thread. One likely means of examining the present objective experimentally might be to try to run the overall exergonic reactions of the oxidative citric acid cycle within the paradigm of hydrothermal reactions under the premise that pyruvate as the energy and carbon source is already available (Matsuno and Nemoto 2005).

Hydrothermal Vent Origin of Life Models

Koichiro Matsuno and Eiichi Imai
Nagaoka University of Technology, Nagaoka, Japan

Keywords

Amino acids · Black smoker · Carboxylic acids · Concentration problem · Hydrothermal vent · Membranous structures · Nucleotides · White smoker

Definition

- [Hydrothermal environments](#) are places where hot water comes into contact with mineral surfaces.

History

Perhaps the first specific proposal (aside from Darwin's offhand reference to a warm little pond (Calvin 1961), which is in some ways a hydrothermal model) for the involvement of hydrothermal environments in the ► [origin of life](#) was that of Harvey in 1924 (Harvey 1924), who suggested that terrestrial thermal springs such as those found in Yellowstone National Park in Wyoming might have been ideal sites for chemical evolution. The idea was resurrected after the 1979 discovery of black smoker submarine hydrothermal sites associated with mid-ocean spreading centers (Corliss et al. 1981). Since its modern resurrection, a wealth of theoretical and experimental studies have examined the idea from various perspectives; nevertheless, the idea remains contentious.

Overview

The resurgence of the hydrothermal model in the late 1970s offered a counterpoint to the long-prevalent Oparin-Haldane heterotrophic model, which had attracted several criticisms. Among them were the notion that the early atmosphere may not have been reducing (in which case the yield of organics from atmospheric synthesis would have been greatly reduced (Schlesinger and Miller 1983)), the possibility that large meteorite impacts might have repeatedly sterilized the surface of the Earth (Maher and Stevenson 1988), and the possible detrimental effects of UV radiation on surface chemistry in the absence of an ozone layer (Berkner and Marshall 1965). Among the proposed benefits of hydrothermal vent environments for the origin of life are thus (1) protection from harsh surface conditions (such as the aforementioned UV radiation and ocean sterilizing meteorite impacts); (2) an abundance of chemical potential in the form of reduced dissolved gases and metals; (3) mineral surfaces to serve as catalysts, adsorbents, and cavities for the production and entrapment of organic compounds; and (4) thermal energy to overcome kinetic barriers to reaction.

It is likely that the geothermal heat flux was greater near the time of the origin of life than at present (Holm 1992); thus, hydrothermal sites were likely more abundant on the early Earth, and they may be more abundant in the modern solar system, for example, in the interiors of Mars and Europa, than are favorable surface environments (CIBA 1996). Furthermore, it has also been suggested that hyperthermophilic archaeobacteria, of the sort typically associated with submarine vents, cluster near the roots of phylogenetic trees (Stetter 2006), supporting the idea that life originated at high temperature, or at least passed through an early high-temperature bottleneck (Arrhenius et al. 1999).

There are a number of potential geochemical settings which are compatible with hydrothermal origin of life models; among them are ► **black smoker** type vents, off-axis type vents, and terrestrial hot spring environments. Black smoker hydrothermal environments have typically very

high temperature ($\sim 350^\circ\text{C}$) and are acidic, reducing, and sulfide rich. Significant amounts of metal sulfides may be deposited in these environments. The eponymous black chimneys are largely composed of metal sulfides which precipitate as the reducing, hot, acidic metal, and sulfide-rich hydrothermal fluids meet the cold ($\sim 2^\circ\text{C}$) oxidizing ambient seawater.

Not long after the discovery of these sites, Wächtershäuser (1988) proposed a pyrite surface model for the origin of life, which suggested life arose based on the attachment of negatively charged molecules such as organophosphates and carboxylic acids (which are ubiquitous in modern biochemistry) to positively charged pyrite surfaces. A series of carbon-fixing reactions were proposed to be catalyzed by these surfaces which allowed for the duplication of the catalytic surface reaction system, which subsequently spread across the mineral surface and complexified over time. This model was not initially explicitly proposed in the context of submarine hydrothermal vents, but the ubiquity of sulfide minerals in such environments quickly led to its being considered in that manner.

Debate soon focused on the extremely high temperatures and low pH values found in such systems, conditions under which most organic compounds are rather unstable (White 1984), which led many to doubt their appropriateness as sites for the accumulation and complexification of organics. After this debate had subsided somewhat, a second type of submarine vent was discovered, the so-called Lost City or peridotite-hosted hydrothermal vent system (Kelley et al. 2001). These environments have typically much lower temperature ($\sim 40\text{--}90^\circ\text{C}$), and the fluid emanating from them is basic (pH 9–11) and quite reducing. Hydrothermal origin of life models has arisen over time to accommodate the conditions more typically found in these environments (see, e.g., Martin and Russell (2007)).

Laboratory simulations of the stability and reactivity of organic compounds under hydrothermal vent type conditions are complicated by the fact that the conditions in these environments range so widely (i.e., from highly reducing to highly oxidizing, from ~ 2 to 350°C , from pH

2 to pH 11, and as fluids are in contact with diverse and variegated mineral surfaces for periods of time ranging from seconds to tens of thousands of years (Holm 1992)).

Some problems which need to be overcome in hydrothermal vent origin of life models include concentrating reactants, synthesizing small organic molecules from dilute solutions under conditions that many organic molecules are unstable, and the polymerization of those monomers into more complex molecules such as peptides, oligonucleotides, and membranes (with the types of molecules specific to the particular model of the proposer).

While many have proposed that complex organic chemistry may occur in deep-sea hydrothermal vent environments, there are a number of obstacles to this. First, the notion that the atmosphere was not particularly reducing stems from the idea that the upper mantle had already released most of its volatiles and its reducing equivalents (largely in the form of metallic and reduced iron) had already segregated into the lower mantle and core (Delano 2001). Thus, although [serpentinization](#) may have been the source of reducing equivalents in hydrothermal systems, their reducing nature was not likely much greater than it is now. Presently, there is some debate over how much of the reduced gases (which consist predominantly of H₂, CH₄, and lesser amounts of ethane, ethane, propene, and propane (Proskurowski et al. 2008)), and this does appear to be in line with equilibration under the reducing environment of the system. However, although the organic molecules detected thus far are extremely depleted in ¹⁴C, suggesting the source of the carbon in them is the mantle derived, the confirmation of the presence of more complex abiotic organic or reduced nitrogen compounds is frustrated by contaminating biological material which becomes entrained as water is drawn into the vent system from neighboring pore sediment water. Thus, it remains uncertain whether even simple organics can be generated in these systems. There is certainly room for further investigation of this possibility.

One suggested the advantage of synthesizing organic compounds in the vicinity of

hydrothermal vents is that many synthetic reactions are calculated to be exergonic at elevated temperatures and pressures. The syntheses of 11 of the 20 protein-forming amino acids were calculated to be exergonic at 100 °C (Amend and Shock 1998). However, Bada et al. (1995), among others, have shown that amino acids are extremely unstable at elevated temperature. Even simple molecules such as glycine have short half-lives at temperatures above 150 °C, and the abundance of such molecules would depend on the balance between their synthesis and degradation. The experimental verification of such syntheses under conditions comparable to those found in natural environments is thus far lacking.

The synthesis of more complex molecules such as nucleotides, oligonucleotides, lipids, or peptides requires that several precursor molecules be brought together. As these reactions are at the very least kinetically second order, they require some concentration mechanism to occur appreciably. One proposed mechanism for solving the concentration problem is thermophoresis in hydrothermal pore systems. Baaske et al. (2007) have theoretically and experimentally discovered model laboratory systems that suggest pore systems inside rocks in the vicinity of ocean hydrothermal vents could enhance the concentration of reactants in pore water with the aid of the marked temperature gradients available there. The enhancement of the concentration is due to the interplay between convective and diffusive flow of solutions in the presence of temperature gradients. Another proposed solution is surface adsorption; however, mineral surfaces are also known to act as catalysts for breaking molecular bonds (Marshall-Bowman et al. 2010), and surface adsorption typically becomes weaker at high temperature; thus, most organics would likely tend to migrate to lower-temperature environments (Cohn et al. 2001), and the residence time of molecules in the high-temperature portion of the systems also requires some experimental verification.

Provided significant starting concentrations of amino acids, peptides can be formed at elevated temperature in water, both with and without condensing agents, as long as the reactions are not

heated for very long. For example, tripeptides of phenylalanine, tyrosine, and glycine have been synthesized at 100 °C in slurries of FeS and NiS as a catalyst in the presence of hydrogen sulfide or methanethiol as a condensing agent (Huber and Wächtershäuser 1998). However, peptides are thermally unstable in water. Below mM concentrations of amino acids, peptides do not form appreciably (Cleaves et al. 2009). Peptides are considerably more stable than oligonucleotides; thus, these sorts of considerations are likely more severe for molecules such as RNA, presenting a disconnect between hydrothermal vent models and RNA World models.

Cycling could overcome some of these problems. For example, molecules could be synthesized during residence in a high-temperature milieu and then quickly quenched into a lower-temperature region. Imai et al. (1999) observed that the synthesis of hexamer of glycine was possible from the cyclic reaction of fairly concentrated solutions of glycine in simulated hydrothermal circulation between 250 and 0 °C. For deep-sea environments, this may be problematic, as the bulk ocean would likely have had a very low concentration of organic compounds (Aubrey et al. 2009). Terrestrial thermal pools may be more favorable in this regard.

There are thus several problems for hydrothermal vent models with respect to organic chemistry. Nevertheless, several lines of evidence point toward an early high-temperature period for life, and there also remain numerous unknown aspects of the types of chemistry which might occur in such environments which warrant further study.

of Technology, Atlanta, GA, USA

Definition

Hydroxy acids are organic compounds containing both hydroxyl and carboxylic acid functional groups. α -Hydroxy acids are a particularly important class of carboxylic acids which have a hydroxyl group on the carbon adjacent to the carboxylic acid group or α -carbon. They may be either naturally occurring or synthetic. Commonly occurring biological α -hydroxy acids include lactic (CH₃CHOHCOOH), glyceric (HOCH₂CHOHCOOH), glycolic (HOCH₂COOH),

and malic (HOOCCH₂CHOHCOOH) acids. α -Hydroxy acids are important metabolic products of the biological transamination of ► [amino acids](#). Several α -hydroxy acids and α -hydroxy acid polyols have been identified in the Murchison meteorite. Some interpret the presence of α -hydroxy acids in this body as evidence for the Strecker-cyanohydrin mechanism for the synthesis of the amino acids also found in it.

Definition

The term hydroxyl group is used to describe the -OH functional group in an organic compound.

Organic molecules containing hydroxyl groups are known as alcohols. Hydroxyl groups are especially important in biochemistry due to their tendency to form hydrogen bonds, as they contain both lone pairs of electrons and a weakly acidic proton. Hydroxyl groups are also able to form hydrogen bonds with water, a property that increases the hydrophilicity and solubility of molecules containing them. The carbohydrates are an example of a group of molecules that are extremely soluble due to hydroxyl functional groups.

Hydroxyl Radical (OH)

William M. Irvine
University of Massachusetts, Amherst, MA, USA

Synonyms

[OH](#)

Definition

The hydroxyl radical, containing single oxygen and hydrogen atoms, is highly reactive. In the terrestrial troposphere, it interacts with and removes a number of pollutants as well as the greenhouse gases methane and ozone. It can damage typical biological macromolecules. As a free diatomic molecule, it is widespread in the ▶ [interstellar medium](#) of our Milky Way galaxy and other galaxies, where it is frequently observed in maser emission. Some external galaxies contain so-called OH megamasers, with luminosity orders of magnitude greater than masers in our Galaxy. In the solar system, OH is a major constituent of cometary comae and an indirect measure of their water content.

History

The OH radical was the first interstellar molecule detected by radio astronomers, in 1963 by Weinreb et al. Measurements of the Zeeman effect for OH transitions have subsequently been used to estimate the magnetic field in the interstellar medium. In 1981, the pure rotational lines of OH were observed at far-infrared wavelengths in absorption against the continuum emission from a background molecular cloud. Cometary OH has been detected both in the ultraviolet and, in 1973, at radio wavelengths; this led to the correct prediction that H₂O ice was present in cometary nuclei and was the source of the hydroxyl radical (through photodissociation by the solar ultraviolet photons).

Hygiea

Hervé Cottin

Univ Paris Est Creteil and Université Paris Cité,
CNRS, LISA, F-94010 Créteil, France

Definition

(10) Hygiea is the fourth largest object of the asteroid main belt, after (1) Ceres, (4) Vesta, and (2) Pallas, the number between brackets being the historical order of discovery of each object. Its mass is 8.7×10^{19} kg, with a density of 2.06 g/cm³, and its size is 450 km × 430 km × 424 km, which makes it a relatively spherical object and considered by some astronomers as a candidate to be recognized as a dwarf planet. Its orbit around the Sun is completed in 5.57 years and is quite eccentric (eccentricity = 0.119) with perihelion at 2.8 ua and aphelion at 3.5 ua. With an albedo of 0.063, Hygiea's surface spectral characteristics are similar to those of the dwarf planet Ceres and match carbon-rich C-type asteroid properties. Due to this spectral proximity and similar densities, it has been proposed that Ceres and Hygiea could share a common origin.

History

(10) Hygiea was discovered in 1849 by Annibale de Gasparis. This first observation occurred rather late compared with other large asteroids such as (2) Pallas or (3) Juno, respectively, discovered in 1802 and 1804. This is due to the relatively low albedo of (10) Hygiea combined with its large distance from the Sun.

Hypercycle

Peter Schuster

Institut für Theoretische Chemie der Universität
Wien, Wien, Austria

Keywords

Autocatalytic network · Hyperbolic growth ·
Major transitions · Dynamical systems ·
Oscillations · Symbiosis

Synonyms

[Cyclic replicator equation](#)

Definition

A hypercycle is a catalytic network of autocatalysts (I_k) that are functionally coupled in a dynamical cycle: $\Rightarrow I_1 \Rightarrow I_2 \Rightarrow \dots \Rightarrow I_n \Rightarrow I_1 \Rightarrow$. Hypercycle dynamics are described by means of nonlinear differential equations of replicator equation type (Fig. 1).

History

The hypercycle was invented in the 1960s (Eigen 1971) as a model for cooperation of otherwise competing elements that are capable of self-replication. Hypercycles were postulated as mechanisms for major transitions in evolution (Eigen and Schuster 1977, 1978a, b; Maynard Smith and Szathmáry 1995; Schuster 1996; Phillipson and Schuster 2009).

Overview

Several replicators ($X_1, X_2, \dots, X_n$) – entities capable of self-replication – form a cyclic catalytic network in which the replication is catalyzed by the precursor element: X_1 catalyzes the formation of X_2 and so on until X_n catalyzes the formation of X_1 . Thereby, the catalytic interactions form

Hypercycle, Fig. 1 The catalytic interactions in a hypercycle with n members. The individual elements, 1, 2, 3, 4, ..., n , are coupled by cyclic catalysis (black arrows): $1 \rightarrow 2$, $2 \rightarrow 3$, $3 \rightarrow 4$, $4 \rightarrow n$, $n \rightarrow 1$. Every member is an autocatalyst as indicated by cycles (small circular arrows)

a closed loop: $1 \rightarrow 2 \rightarrow 3 \rightarrow \dots \rightarrow n \rightarrow 1$. The simplest theoretical example is the *elementary hypercycle*, which in mathematical terms is described by the differential equation

$$\frac{dx_j}{dt} = x_j \left(f_j x_{j-1} - \sum_{i=1}^n f_i x_{i-1} x_i \right); \quad (1)$$

$$i, j = 1, 2, \dots, n \text{ and } i, j = \text{mod } n$$

which is a special case of replicator equations (Hofbauer and Sigmund 1998; Nowak 2006). The variables are normalized concentrations of replicators, $[X_j] = N_j$ and $x_j = N_j / \sum_{i=1}^n N_i$ with $\sum_{j=1}^n x_j = 1$. The parameters f_j are rate parameters of the catalyzed replication reactions, $(A) + X_j + X_{j-1} \rightarrow 2X_j + X_{j-1}$, where (A) stands for the building blocks for the synthesis.

Hypercycle, Fig. 2 Hypercycle dynamics visualized in form of solution curves of Eq. 1. Normalized concentrations of the members of hypercycles $x_j(t)$ are plotted as functions of time t for different sizes of the cycle. Individual members (different colors) cooperate in the reproduction of the entire cycle. Different dynamics is observed for different sizes: $n = 2$, the concentrations approach their stationary values monotonously; $n = 3$, the concentrations approach the stationary values with strongly damped oscillations; $n = 4$, the

concentrations approach the stationary values with weakly damped oscillations; and $n = 5$, the concentrations oscillate without damping. For $n > 5$, hypercycle dynamics shows oscillations without damping as illustrated here for the $n = 5$ case. The following parameter values were chosen: $f_1 = f_2 = f_3 = f_4 = f_5 = 1$; initial conditions, $x_1(0) = 0.95$ and $x_2(0) = 0.05$ for $n = 2$ and $x_1(0) = 0.9$ and $x_k(0) = 0.1/(n-1)$ for $n = 3, 4, 5$

The qualitative features of solutions of Eq. 1 do not depend on particular values f_j (as long as they are strictly positive, $f_j > 0$, Hofbauer and Sigmund 1998). Without losing generality, all f_j values are chosen to be equal, and the dynamical system has a stationary point in the middle of concentration space: $x_1 = x_2 = x_3 = \dots = x_n = 1/n$. The solution curves $x_j(t)$ show characteristic dependence on the size of the hypercycle (Fig. 2):

1. For $n = 2$, the dynamical system converges monotonously to a unique and asymptotically stationary state at which both replicators X_1 and X_2 are present.
2. For $n = 3$ and $n = 4$, the stationary state is unique and asymptotically stable. The solution curves $x_j(t)$ show strongly damped oscillations $n = 3$ and weak damping for $n = 4$.
3. For $n \geq 5$, the stationary state is unstable and the concentrations $x_j(t)$ oscillate.

Independently of internal dynamics, the total concentrations of hypercycles as integral units, $C(t) = \sum_{i=1}^n N_i(t)$, grow stronger than exponential for unlimited resources. This *hyperbolic growth* is observed for a class of systems in which the population size has an enhancing effect on the growth rate. Examples of hyperbolic growth were observed in virology, in demography (growth of human population), and in economics (*increasing returns*). Systems with hyperbolic growth outgrow exponentially growing systems, since in theory a hyperbolically growing population can reach infinity in finite times. Once a hypercycle has been established, it is very hard to replace it by another system: hypercycles are candidates for *once-and-forever* decisions. Examples for hypercycles in the real world are symbioses and other forms of cooperation within and between species. Formation of hypercycle-like networks among cooperative RNA replicators has been reported (Vaidya et al. 2012).

Hypersaline Environment

Felipe Gomez

Centro de Astrobiología (CSIC/INTA), Instituto Nacional de Técnica Aeroespacial, Torrejón de Ardoz, Madrid, Spain

Definition

Hypersaline environment is an extreme habitat dominated by high salt concentration. Associated to this extreme condition, other extreme conditions can be found like low oxygen concentration and alkaline conditions. The inhabitants of these environments are microorganisms that are called

“halophiles.” Halophiles have to solve the problem of the osmotic pressure generated in the cell membrane. To do that, they can use compatible solutes. Different groups can be distinguished on the basis of their physiological responses to salt. Several classifications have been proposed; one considers the optimum growth of the microorganisms at different salt concentrations: non-halophiles are those that grow best in media containing less than 0.2 M NaCl, halotolerant microorganisms that can tolerate high salt concentrations, moderate halophiles growing between 0.2 and 2.5 M NaCl, and extreme halophiles growing in optimal conditions at high salt concentration (2.5–5.2 M NaCl).

Definition

The word hyperthermophile (literally extremely heat loving) refers to a microorganism that has

an optimum temperature for growth above 80 °C. Most hyperthermophiles belong to the Archaea domain, with only few exceptions belonging to Bacteria.

History

Thomas D. Brock (1978) isolated the archaeal genus *Sulfolobus* at Yellowstone National Park and showed that it grew optimally at 75 °C with an upper temperature limit for growth at 85 °C. Previous reports by the same author described prokaryotic microorganisms that were able to grow on microscopy slides inside boiling (92 °C) hot springs. These organisms probably were true hyperthermophiles. However, the first hyperthermophiles isolated and characterized in the laboratory (*Methanothermus fervidus* and the *Thermoproteus* spp.) were isolated from hot springs in Iceland and described simultaneously in 1981 in two articles coauthored by Karl O. Stetter and Wolfram Zillig (Zillig et al. 1981; Stetter et al. 1981). In the following two decades, further work led mainly by K. O. Stetter focused on submarine or subterranean thermal environments. This work allowed the isolation and description of more than 50 species of hyperthermophilic Archaea and a few Bacteria, some requiring temperatures above 90 °C to grow, with optimum temperatures above 100 °C. Phylogenetic analysis based on 16S RNA revealed that all of them are slowly evolving groups, supporting an ancient origin for this type of microorganisms.

Overview

Since the first descriptions of hyperthermophiles in 1981 (Zillig et al. 1981; Stetter et al. 1981), about 90 species of hyperthermophilic Archaea and Bacteria have been described from different terrestrial and marine thermal environments. Taxonomically and despite the existence of yet unassigned isolates, most are grouped in ten orders (Archaea: Thermoproteales,

Desulfurococcales, Pyrodictiales, Thermococcales, Archaeoglobales, Methanococcales, Methanobacteriales, Methanopyrales; Bacteria, *Aquificales* and *Thermotogales*). A few hyperthermophilic isolates are even unable to grow below 80–90 °C. Despite this, it has been possible to isolate hyperthermophiles far from the nearest known thermal effluent, probably because they remain viable for years at low temperatures. At the upper part of the temperature range, there are hyperthermophiles that can tolerate temperatures normally used in sterilization processes (121 °C) for 1 h (*Pyrodictium occultum*). Kashefi and Lovley (2003) reported residual growth of a hyperthermophilic isolate under such conditions.

The use of different phylogenetic markers assigns the hyperthermophiles to the root of the corresponding evolutionary trees, leading to the hypothesis that this kind of microorganism is very ancient. Despite this generally accepted view of the phylogenetic tree, the slow-evolving character of hyperthermophiles has been challenged by different studies in the last decade based on other phylogenetic approaches (Ciccarelli et al. 2006). According to this view, hyperthermophilic character could be an adaptation of moderate **thermophiles** to superheated environments, in some cases through lateral gene transfer.

Adaptation to hyperthermophilic conditions is the result of a series of specific modifications of the structures and macromolecules of the cell, as simple metabolites and cofactors are basically the same as those of mesophiles. Membrane adaptation results from an increase in the hydrophobic lateral interactions between the major lipids, esters of glycerol and two fatty acids in Bacteria, and ethers of glycerol and two isoprenol-derived alcohols in Archaea. In hyperthermophilic Archaea, bipolar tetraether lipids form membrane monolayers in which C40 isoprenols are frequently cyclized as a further thermal adaptation. A low DNA content (1.8–3 Mbp) and the presence of histone-like proteins have been described in some hyperthermophilic Archaea. The presence of type I topoisomerase that introduces positive coils (reverse gyrase) into DNA is the only trait common

to hyperthermophilic Bacteria and Archaea, leading to the hypothesis that DNA stability is an important factor for life at high temperatures. However, *Thermococcus kodakaraensis* mutants lacking this activity show only a slight decrease in growth rate above 90 °C, so it has been proposed that this enzyme could help to rewind ssDNA regions separated by thermal stress (Sandman 2008). Enzymes from hyperthermophiles usually have an activity profile that fits the temperature growth range of the organism of origin as the result of a higher number of intra- and intermolecular interactions (Vieille and Zeikus 2001).

Most hyperthermophiles grow as obligate or facultative chemolithotrophs by using either hydrogen or sulfides (e.g., pyrite) as electron donors and nitrate, CO₂, sulfur, sulfate, or ferric iron as electron acceptors to gain energy. Low concentrations of oxygen are also used by some isolates, but for most hyperthermophiles oxygen is highly toxic at or near their temperature of growth. Carbon assimilation by hyperthermophiles growing chemolithotrophically takes place on CO₂ or CO mainly through the reductive acetyl coenzyme A cycle (acetyl-CoA or Wood-Ljungdahl pathway), like in many anaerobic Gram-positive bacteria, or through the reductive tricarboxylic acid cycle (rTCA or Arnon cycle), as in green sulfur bacteria, although alternative modified pathways also exist. These cycles usually generate acetyl coenzyme A, from which gluconeogenesis must start. The presence of an irreversible condensing fructose biphosphate aldolase/phosphatase is a generalized trait within autotrophic hyperthermophiles that appears to be an essential step to guide these pathways toward gluconeogenesis (Say and Fuchs 2010). Facultative and obligate chemoorganotrophs also exist among hyperthermophiles that grow by anaerobic respiration, essentially with elemental sulfur (S⁰) as electron acceptors or, more rarely, by fermentation (i.e., *Thermoproteus uzonensis*). Data obtained from the analysis of thermophilic environments using molecular ecology methods (Pagé et al. 2008) suggests that the biodiversity of chemoorganotrophic hyperthermophiles is underestimated.

Basic Methodology

The high sensitivity to oxygen of hyperthermophiles at their growth temperatures is an important challenge for their isolation. Environmental samples to be used for the isolation of hyperthermophiles (water, soil, rock, etc.) have to be taken under reducing conditions to prevent any contact of microorganisms with oxygen at least at high temperature, when its toxic effect is more severe. For terrestrial surface environments, taking samples does not require sophisticated equipment. In the absence of N_2 gas, reductants such as sodium sulfide/sodium dithionite and an appropriate redox indicator such as resazurin can be added to sample glass containers, which have to be tightly closed with gas-impermeable butyl rubber stoppers. Samples can then be transported to the laboratory at room temperature. For under-sea hot environments, perforation drills, water samplers, piston corers, grab samplers, and dredge samplers or even deep submergence vehicles (DSVs) and remotely operative vehicles (ROVs) are required. Numbers of whole microbial communities in different submarine hydrothermal samples range from 10^4 to 10^9 cells per gram at the surface of ► [black smoker](#) chimneys, sediments, and hydrothermal plumes. Superheated vent fluids can range from undetectable numbers up to 10^6 cells per ml (Nakagawa and Takai 2006).

Once at the laboratory, isolation of new hyperthermophiles requires enrichment cultures subjected to conditions mimicking those of the environment at the sampling site regarding temperature, putative electron donors and acceptors, and carbon sources. Growth rate is a limiting factor for successful enrichment, and periods of days are usually required before attempting the isolation of individual cells. Due to obvious difficulties in keeping solid media under the prescribed conditions, most isolation procedures require liquid medium and use either dilution or physical methods such as optical tweezers. For high scale production, special fermenters have been designed to withstand the harsh growth conditions that most hyperthermophiles require,

which in some case combine high temperatures and pressure in acidic media (Stetter 2006).

Key Research Findings

The main interest of hyperthermophiles is based on two key observations. On the one hand, they were and still are regarded as ancestral organisms, giving an opportunity to analyze what are most likely “living fossils” from the Archaean era. This view is still the most accepted hypothesis, although an alternative hypothesis has been proposed. On the other hand, a search for the temperature limits for life has driven the search quest for more thermophilic microorganisms. Today, the upper temperature limit for growth of a well-established and described microorganism is 113 °C for *Pyrolobus fumarii* (Blöchl et al. 1997), whereas description of an isolate able to grow at 121 °C is still under discussion (Kashefi and Lovley 2003). A further area of research on hyperthermophiles is focused on the impressive thermostability of their enzymes and their possible use in industrial processes. This thermostability is also responsible for the ease with which their proteins and macromolecular complexes crystallize under laboratory conditions, raising additional interest that led to develop large structural genomics projects (Jenney and Adams 2008).

Applications

The high stability of enzymes under high temperatures (there are enzymes active above 125 °C) is associated with an increase in compactness that results in increased resistance to additional stresses such as the presence in the reaction of detergents or organic solvents (Vieille and Zeikus 2001). Such combination of resistances fits specific applications in different fields. For example, DNA polymerases from hyperthermophiles (*Pyrococcus* sp., *Thermococcus* sp.) are commonly used to amplify DNA sequences with high fidelity. Other enzymes from hyperthermophiles are or have

the potential to be used in industrial processes for which high temperatures represent an added value, such as starch and cellulose hydrolysis and further sugar modification (endoglucanases, glucosidases, xylanases, amylases, glucoamylases, pullulanases, etc.), proteases for detergents, lipases and esterases for biocatalysis, oxidoreductases like alcohol or glutamate dehydrogenases for biotransformations, C-C bonding enzymes (aldolases, transketolases), nitrile-degrading enzymes, etc. (Antranikian 2008). Additional applications in specific but robust biosensor devices or for nanotechnology are also in development. In addition to the enzymes, hyperthermophiles produce special kinds of compatible solutes such as mannosyl glycerate, cyclic 2,3-biphosphoglycerate, and diglycerol phosphate in relevant amounts, some of which have been shown to confer thermoprotection and protection against desiccation to mesophilic enzymes (Santos et al. 2008).

Future Directions

Given the biological and applied interest of hyperthermophiles, future research in the field will develop several lines of interest. Their ancient nature and extreme form of living require a comprehensive physiological study of at least a pair of model organisms, for which a reliable system for genetic manipulation should be developed. Present developments on *Thermococcus kodakaraensis* and *Sulfolobus solfataricus* are at the front lines of this effort. The construction of efficient systems for the overexpression of genes in such models will widen the number of hyperthermophilic enzymes available for applications that at present are hidden because of the inability to produce them in mesophilic hosts. Such expression systems will also be required to crystallize some of these proteins and complexes. Also, the metagenomic approaches on hyperthermophilic environments will open up a new world of enzymes having biotechnological potential to help to optimize existing processes and develop new

ones. Finally, molecular ecology methods in such environments will likely unveil the presence of new non-cultivable hyperthermophiles that could uncover some phylogenetic surprises. Hyperthermophiles are of special interest for astrobiology because high-temperature processes are important factors in the development of planetary bodies; thus, the scenarios in which life can develop in the universe increase correspondingly.

Definition

Hypoliths are organisms or communities of organisms that live on the underside of rocks or at the rock-soil interface.

Overview

In hot and cold deserts, the underside of rocks can provide a refugium for microorganisms, both photosynthetic (cyanobacteria and algae) and non-photosynthetic (Cameron and Blank 1965; Schlesinger et al. 2003). The organisms are referred to as “hypoliths.” The community is termed “hypolithon” (following the terminology for endoliths by Golubic et al. 1981). The photosynthetic components of hypoliths include organisms adapted to extreme rock habitats including *Chroococcidiopsis* and *Gloeocapsa* species. Hypoliths often display well-defined “bands” of growth on the underside of rocks or in the case of thin rocks, complete colonization of their underside. As photosynthetic microorganisms provide a source of carbon for heterotrophic microorganisms, the hypolithic colonization of translucent rocks by photosynthetic microorganisms can indirectly benefit non-photosynthetic microorganisms (Smith et al. 2000). Hypolithic colonization of quartz stones has now been documented in many locations, for example, the Vestfold Hills, Antarctica (Smith et al. 2000); the Mojave Desert, USA (Schlesinger et al. 2003); the Negev desert, Israel (Berner and Evenari 1978); the Namib Desert, Africa (Budel and Wessels 1991); and the deserts of China (Warren-Rhodes et al. 2007). On the underside of rocks, organisms gain a range of advantages compared to surface organisms, such as protection from UV radiation (Cockell et al. 2003). In the Antarctic polar desert, the stones warm the hypolithic biota and, during the summer, mitigate freeze-thaw (Broady 1981). Quartz stones in the Vestfold Hills, Antarctica, could provide temperatures 10° in excess of ambient air temperatures (Smith et al. 2000). For photosynthetic organisms, the limiting factor for the thickness of rocks under which photosynthetic microorganisms can grow is set by the thickness

Hypolithic, Fig. 1 An example of a community of photosynthetic hypoliths inhabiting the underside of opaque rocks in the Canadian High Arctic

H

that reduces light levels to below those required for ► [photosynthesis](#). Investigations on the colonization of the underside of translucent flint in the Negev desert showed that the more translucent flint types were colonized in a greater number of instances compared to less translucent flints (Berner and Evenari 1978). Less than 0.01% of incident light penetrated to below 40 mm in quartz rocks in the Negev (Berner and Evenari 1978), and light was reduced to 0.08% of incident under 25 mm of quartz rock from the Mojave desert (Schlesinger et al. 2003). At these depths colonization became limited. Broady found similarly large attenuations under Antarctic quartz rock (Broady 1981). The moisture availability in the hypolithic habitat is also an important determinant of which rocks are colonized and their ecological distribution in the environment (Warren-Rhodes et al. 2007). Hypoliths are also found under opaque rocks in polar deserts (Cockell and Stokes 2004). Greater than 90% of rocks examined were colonized. Periglacial processes can cause movements in rocks, which in turn create openings around the edges of rocks that allow the penetration of photosynthetically active radiation to the underside of rocks. These processes allow for the colonization of rocks with productivity of these communities potentially as high as the above-ground productivity accounted for by plants (see Fig. 1).

Hypoxanthine

Shin Miyakawa
Kamagaya, Chiba, Japan

Synonyms

[\\$16-Hydroxypurine](#)

Definition

Hypoxanthine ($C_5H_4N_4O$, molecular weight: 136.11) is a naturally occurring purine base. It is occasionally found as a constituent of nucleic acids such as tRNA. The half-life of hypoxanthine to hydrolysis is 12 days at 100 °C and 5,000 years at 0 °C at pH 7. It has a UV absorption maximum at 249.5 nm (pH 7). It has been found in the Murchison meteorite and is synthesized by hydrolysis of ► [adenine](#), in HCN polymerizations, and in discharge experiments using gas mixtures such as CO–N₂–H₂O. The ribonucleoside of hypoxanthine is named inosine.

Synonyms

[International Astronautical Federation](#)

Definition

In September 1950, Alexandre Ananoff from the “Groupement astronautique français” convened the first International Astronautical Congress (IAC). Eighteen representatives from the astronautical societies of eight countries (Argentina, Austria, Denmark, France, Germany, Spain, Sweden, and the UK) decided to set up an association to secure future international cooperation. The International Astronautical Federation (IAF) was formally established at the second IAC organized by the British Interplanetary Society (BIS), in London, in 1951.

Every year since then, the federation, together with the International Academy of Astronautics (IAA) and the International Institute of Space Law (IISL), has organized the International Astronautical Congress, which encourages the advancement of knowledge about space. It is held in connection with a major space exhibition. IAC is now recognized as the main international conference on space activities. More than 1600 technical papers on space programs and research activities around the world are presented in various sessions. The IAF maintains an online archive of past congress papers and presentations to provide members with a historical record of global space activities.

In 2020 the IAF had 407 members from 71 countries. The organizations involved include astronautical and other professional societies, space agencies and international organizations, companies from the space industry, universities and other research institutions, and nonprofit organizations interested in space matters.

lapetus

Therese Encrenaz
XLESIA, Observatoire de Paris – Section de Meudon, Meudon, France

Definition

Iapetus was discovered in 1671 by Giovanni Domenico Cassini; it is the outermost mid-sized

icy satellite of ► [Saturn](#). Its distance to Saturn is 3,560,000 km (or 59 Saturnian radii), and its diameter is 1440 km. Its density is 1.02 g/cm³, indicating a very low rock/ice ratio. Iapetus is unique in its albedo distribution, which is very low on Iapetus’ leading side in its orbit around Saturn and ten times higher on the opposite side. It has been proposed that the dark material could be due to the permanent accretion of matter coming from the neighboring satellite ► [Phoebe](#), which is also very dark. Another possible explanation is that the low albedo of Iapetus could be a result of organic deposits formed from methane ice impacted by dust particles.

Definition

The International Astronomical Union (IAU) was founded in 1919 with the mission of promoting and safeguarding the science of astronomy in all its aspects through international cooperation. More than 12,000 professional astronomers (active in professional research and education) from all over the world, at the Ph.D. level and beyond, are IAU members. The IAU is financed

by academies or equivalent institutions of its 79 member countries.

Overview

The scientific and educational activities of the *IAU* are organized by its nine scientific divisions and some 35 specialized commissions (e.g., commissions devoted to Astrobiology, History of Astronomy, Stellar Evolution, The Local Universe) that cover the full spectrum of Astronomy. The long-term policy of the *IAU* is defined by the triennial General Assembly and implemented by the Executive Committee, while the day-to-day operations are directed by the *IAU* officers. The *IAU* Secretariat is hosted by the Institut d'Astrophysique de Paris, France.

The key activity of the *IAU* is the organization of scientific meetings, including nine international *IAU* Symposia every year, with additional symposia and other meetings every 3 years at the General Assembly. The *IAU* is also responsible for the definition of fundamental astronomical and physical constants, unambiguous astronomical nomenclature, promotion of educational activities in astronomy, and informal discussions on the possibilities for future international large-scale facilities. Furthermore, the *IAU* serves as the internationally recognized authority for assigning designations to celestial bodies and surface features on them. The *IAU* is a member of the International Council for Science (ICSU).

Ibn Battuta Desert

Definition

Ibn Battuta Desert is an informal term applied to the arid lands in Morocco extending from the Southern slope of the High Atlas to the North up to a desertic area rich of sebkhas (dry lakes) near Tarfaya to the South. The Ibn Battuta Desert stretches to the East from the Tafilalet (Erfoud, Rissani) up to the Atlantic Coast. Astrobiological field research have been performed in several locations, of which the most interesting are: (i) Hamar Laghdad -Kess Kess- (Tafilalet) near Erfoud (31°22'42"N 4°03'03"W); (ii) sebkhas in desert belt along the Atlantic coast South of the town of Tarfaya. (iii) the El Bordj carbonate body, Silurian in age, which represent the oldest chemosynthetic deposits so far recognized on Earth (33°03'58"N 5°36'41"W).

Overview

The Ibn Battuta Desert has been used by the Ibn Battuta Centre (www.ibnbattuta.org) for a large number of activities including rover mobility tests, entry, descent and landing (EDL), spacecraft operations, instrument testing for Martian mission, human Martian exploration, and geological features.

One of the main astrobiological setting in the informal Ibn Battuta Desert is the Hamar Laghdad located in Tafilalet near Erfoud, consisting of a ridge with cluster of mounds called Kess Kess (Fig. 1). These mounds, Middle Devonian in age, are interpreted as mud volcanoes produced by hydrothermal activity. They have been studied for several decades and recently, several authors suggested a strong astrobiological relevance due to the purported hydrothermal chemosynthetic origin. This unit has been firstly described by Roch (1934) whereas Brachert et al. (1992) provided a detailed sedimentological analysis. More recently, laboratory and paleontological evidence support a hydrothermal interpretation with a possible contribution by methane (Belka 1998; Joachimski et al. 1999; Cavalazzi et al. 2012; Guido et al. 2013; Franchi et al. 2015). A mound slightly younger than Kess Kess, the Hollard

Ibn Battuta Desert, Fig. 1 A panoramic view of the Kess Kess carbonatic mounds

Ibn Battuta Desert, Fig. 2 The Hollard Mound where it is possible to see a section of the internal structure: the internal core formed by a vertical chimney is surrounded

by inclined strata that represent the slope of the mound. The section shows clear evidence of a formation due to sedimentary volcanic processes

Ibn Battuta Desert, Fig. 3 A view of the Sabkha Oum Dbâ in foreground the steep wall of the margin of the depression and the central evaporites

Ibn Battuta Desert, Fig. 4 The travertine cascade at the Southern end of Sabkha Oum Dbâ. The smooth morphology is produced by calcareous layering, microbial/algal mats and vegetation

Mound (Fig. 2) (Hollard 1981), shows clearly evidence of a cold seep origin. The Kess Kess represent the most prominent examples of mud

Ibn Battuta Desert, Fig. 5 A sample from the bottom of creeks at the southern margin of Sabkha Oum Dbā. The top brown layer is an algal mat with diatoms and cyanobacteria. Immediately below there is a thin green layer mostly formed by cyanobacteria. The dark material below is a mixture of mud and cyanobacteria in an anoxic environment

volcanoes that have been active through the Devonian and Carboniferous in this area that was a shallow water embayment of the Paleozoic Ocean. They represent a quite unique case of this type of environments.

Another area with a strong astrobiological interest lies in the scattered sebkhas in the desert belt along the Atlantic coast South of the town of Tarfaya. The area is scattered by sabkhas (evaporitic dry lakes) that could be similar to the ones that may have produced evaporitic sediments on Mars. This area has attracted the attention of astrobiologists only recently (Barbieri and Cavalazzi 2018) with a program managed by the Ibn Battuta Centre. The area shows complex morphologies and environments. The sebkhas are localized inside depressions several tens of meter deep (Fig. 3). Evaporitic deposits are usually concentrated in the middle and the margins are covered by clastic, mostly, wind-blown deposits. Associated with the evaporites there are travertine deposits that, in one case, form an active travertine

cascade (Fig. 4). Bacterial mats colonize the cascade itself and deposits downstream as well (Fig. 5).

In this area, geochemical research work has been carried on reg (deflation surfaces) deposits (Oberlin et al. 2018). Even the aeolian bed forms show evidence of biological activities in the

coastal area (near Tarfaya) with the formation of bacterial mats in the slip face of dunes. The effect is to “cement” the sand that is then eroded by the avalanching movement of the sand (Fig. 6).

A geological unit of strong astrobiological interest is the El Bordj carbonate body, Late

Silurian in age, which is the oldest chemosynthetic deposits so far recognized on Earth (Fig. 7). The El Bordj body is actually located outside the Ibn Battuta Desert at its border in the Middle Atlas. It was firstly described by Ager et al.

(1976), whereas Campbell and Bottjer (1995) suggested a possible chemosynthetic origin based on the presence of an extensive brachiopod community. Barbieri et al. (2004) with a compelling analysis have recognized this body as cold-seep in origin with methane mediation. Brachiopod accumulations (Fig. 8) form the bulk of the body that are matched also by stromatolites. Due to some agricultural work that has exposed a larger area of the body, Jakubowicz et al. (2017) have been able to recognize large modiomorphid bivalves associated with atrypid brachiopods. This finding confirms the chemosynthetic origin of these deposits.

The Ibn Battuta desert displays a number of other astrobiological sites and features such as the Cambrian stromatolites (Fig. 9), South of Ouarzazate where it is possible to see them in growing 3D position (Fig. 10).

Washington, DC, USA

Center for Chemical Evolution, Georgia Institute of Technology, Atlanta, GA, USA

Definition

In chemistry, ice refers to water in a solid crystalline phase, the common form of which encountered at normal terrestrial temperatures and pressures is known as Ice I *h*. There are 16 known crystalline phases of water ice, most of which are only known to occur at very high pressures, pressures which may be encountered in the interiors of large icy planets or moons, although one other phase, Ice XI, has been observed in some Antarctic glaciers. Ice I *h* is the only known nonmetallic substance which expands as it freezes, being some 9% less dense than liquid water at 273 K. This is due to hydrogen bonding in the crystal lattice which forces the molecules into positions farther apart than normally occurs in the liquid phase. This change in volume contributes to water's activity in the mechanical

weathering of minerals and also causes ice to float when frozen.

In planetary science, and more generally in astronomy, an ice refers to a volatile (a species with a low boiling point, such as N_2 , water, CO_2 , NH_3 , H_2 , CH_4 , and SO_2) with a melting point above ~ 100 K. The solid phases of these ices can be glasses (which are technically extremely viscous liquid phases) or crystalline solids, depending on the temperature, pressure, and rate at which the ice forms. Ices observed or expected to be present on the mantles of interstellar dust grains include, in addition to water, CO , CO_2 , CH_3OH , CH_4 , NH_3 , O_2 , and N_2 . Ices reported on the surfaces of satellites in the outer solar system and of Kuiper Belt Objects include H_2O , CH_4 , N_2 , CO , CH_3OH , and perhaps other volatile organics such as ethane.

Definition

Ida is a main-belt asteroid of the Koronis family, originating from the breakup of a larger parent body. It orbits the sun between the orbits of Mars and Jupiter at an average distance of 2.86 AU with one orbit taking about 4.84 years. Ida has a rotation period of 4.63 h. Elongated in shape, its average diameter is about 32 km. It is accompanied by its moon Dactyl which has an average diameter of 1.2–1.6 km. Dactyl's orbit provided constraints for Ida's density to $2.6 \pm 0.5 \text{ g/cm}^3$. Ida's mass is estimated between 3.65 and $4.99 \times 10^{16} \text{ kg}$.

Ida has been classified as spectral S-type asteroid. The irregular surface of the asteroid is heavily cratered and covered by regolith composed of silicate minerals. Ida exhibits space weathering where older parts of the surface turn reddish. Based on cratering records, Ida's surface seems more than 1 billion years old, whereas the Ida-Dactyl system is estimated to be less than 100 million years of age considering the collisional life expectancy of Dactyl.

History

Ida was discovered in 1884 by the Austrian astronomer Johann Palisa in Vienna. It was visited and imaged in 1993 by the Galileo spacecraft. Ida’s moon Dactyl, the first confirmed satellite of an asteroid, was discovered in February 1994 by Ann Harch from Galileo’s imaging team.

Synonyms

Magmatic rock

Definition

An igneous rock forms by crystallization of magma. There are two main types: *effusive*

volcanic rocks that crystallize or solidify from erupted lava or fragmental (pyroclastic) material that reaches the surface of the Earth, at contact with the atmosphere and/or the hydrosphere; *plutonic or intrusive rocks* which crystallize from magma that did not reach the surface. These two types are distinguished by their grain size: *effusive volcanic rocks* are fine-grained or even glassy because they cool rapidly following eruption at the Earth’s surface; rare crystals typically float in a fine-grained matrix; *intrusive plutonic rocks* are coarse-grained and typically show an interlocking fabric because they crystallize slowly in a thermally insulated environment. Common minerals in igneous rocks are ▶ *olivine*, pyroxene, amphibole, mica, plagioclase, feldspar, and quartz. Common intrusive rock types include ▶ *peridotite*, ▶ *gabbro*, granodiorite, and ▶ *granite*; their volcanic equivalents are ▶ *komatiite*, ▶ *basalt*, andesite, and rhyolite, respectively.

Brethren of purity

Overview

The Brethren of Purity (*Ikhwan al-Şafa'*) were a group of anonymous authors who composed a collection of 50–52 epistles (the last two may have been later additions by the same or other authors), which became well-known from the late ninth century. Contemporary Shiite Isma'ili scholars and authors claimed the epistles to be composed by Isma'ili missionaries – a claim that went uncontested by their contemporaries. This Isma'ili attribution combined with internal evidence suggest that the epistles were either fully or largely completed before the establishment of the Isma'ili Caliphate in 909.

As a collection, the Epistles attempted to encompass all branches of knowledge. The 52 Epistles were grouped into four sections, sometimes called books: “mathematical sciences” (14 epistles), “corporeal and natural sciences” (15 epistles), “sciences of the soul and intellect” (ten epistles), “Divine and legal sciences” (11 or 12 epistles). Ikhwān al-Şafā addressed astronomical and cosmological considerations in the second book, especially in its second epistle (16 overall). Ikhwān al-Şafā endorsed the concept of the celestial animal, which Ptolemy presented in his *Planetary Hypotheses*, and which had important Stoic roots. Similar to an animal or a human, the universe with its different orbs is animated by the universal soul, which leaves it at the end of times, much like the departure of a human or animal soul signals the end of life for that given being. Their discussion of the universal soul, and the end of the universe at the end of times, departed from Aristotelian views on the infinity of the universe which were common among philosophers at the time, and share the convictions of the theologians (*mutakallimīn*).

Although Ikhwān al-Şafā's writings betray strong Pythagorean and Neo-Platonic influences,

their cosmological and astronomical discussions largely accepted Aristotelian and Ptolemaic models that were dominant in the Greco-Islamic context of the time. They accepted the universal circular motion of planets as caused by the movement of the outer orb, which is moved by the Prime Mover. Motion was transferred downwards from outer to inner orbs, making lower planets slower than the upper planets. They unequivocally refused any notion of contradictory or retrograde motion, insisting that all planets moved in the same direction in perfect circles. They appeared to have objected to Ptolemy's eccentrics, although they fully endorsed epicycles as perfect explanations of the planets' retrograde motion and of apparent change in their size and brightness. Ikhwān al-Şafā accepted the Aristotelian notion of a different nature for celestial beings. However, they explained that this nature was limited only to their being incorruptible, and that they exhibited many of the other qualities of bodies in the sub-lunar sphere. These similarities appeared to provide enough justification for celestial influences on beings in the sublunar sphere, thus legitimizing astrology. They rejected the existence of empty space whether inside or outside the universe.

While the Epistles represented an encyclopedic collection that addressed all essential branches of knowledge at the time, they had a central goal of self-improvement that held through the entire collection. They also maintained a clear understanding of prophecy and the Imamate and their role as conduit of universal divine knowledge, the difference between the Select and the Commoners in relation to knowledge, and the role of knowledge as the central component of faith and pious living.

Definition

Imaginary voyages are fictional travel accounts or narratives, commonly expressing utopian ideas and satirical comments on the contemporaneous society.

History

A kind of imaginary voyage is the space travel narrative using current scientific knowledge, often in combination with satire, political critique, utopian dreams, and philosophical reflection. The dream of flying and leaving this Earth is archaic. The Chinese emperor Shun more than 4000 years ago, according to a legend, fled to safety in a parachute. The Old Testament tells of Elijah taken up to heaven by angels in a chariot of fire. In Greek myth, the inventor Daedalus designed wings of feathers and wax in order to escape, together with his son Icarus, from the labyrinths of King Minos. Icarus flew too close to the Sun, so that the wax melted and he soon fell into the sea.

Ancient cosmology did not give much scientific support for the existence of extraterrestrial life. Aristotelian physics and the Ptolemaic geocentric model made a sharp distinction between

the Earth and the heavens. Notwithstanding, imaginary space voyages exist in antique literature. The Roman author Marcus Tullius Cicero's *Somnium Scipionis* (The Dream of Scipio) from the first century BCE tells about a journey taking place in the dreams in which the soul is liberated from the body and travels into space.

What could be described as the first detailed space travel narrative is the Syrian satirist Lucian of Samosata's *Alēthē diēgēmata* (A True Story), written in the second century CE. *A True Story* is indeed a satire, a parody that alludes to the fantastic travelogues, fictional journeys, miracles, and fables told in the Greek archipelago. Lucian, however, admits that he is lying, but claims also that he is far more honest than other liars, because he tells us that he is lying. He and his crew travelled through the Pillars of Hercules – the Strait of Gibraltar – in curiosity and longing for adventure. A whirlwind pulled the ship into the air and they sailed for seven days and seven nights. On the eighth day, they came to a large land that resembled an island shining with a bright glow. The land was inhabited and cultivated. It was the Moon. Below them they saw another land with cities, rivers, seas, forests, and mountains. It was their own world. They then became entangled in a battle between the armies of the Moon and the Sun. Lucian seconded the Moon king against the Sun king. The Moon people, Lucian reports, are not born of women, but of men, and men marry there with men, and they carry their unborn children not in the belly, but in the calf. The Lunarians eat smoke and drink air. Lucian assures that anyone who does not believe him will realize, if one ever comes to the Moon, that he is telling the truth.

The scientific revolution in the sixteenth and seventeenth century changed the human view of the world, the universe, and humankind's place in the creation. Imaginary space voyages became a popular genre. There were basically three reasons that made space travel more conceivable and appealing: (i) new scientific explanations of the planetary motions, the heliocentric worldview making Earth a planet among other planets; (ii) new inventions, the telescope by which one could gaze at distant celestial bodies, finding a topography of the Moon similar to the geography

of Earth; and (iii) the discovery of new worlds and foreign people and cultures, such as the European rediscovery of America, the "New World" in 1492 and of the southern continent Australia in the seventeenth century.

The Aristotelian-Ptolemaic worldview was challenged in 1543 by the Polish astronomer, Nicolaus Copernicus. In his ground-breaking work, *De revolutionibus orbium coelestium* (On the Revolutions of the Celestial Spheres), Copernicus put forward a heliocentric model in which the Sun is at rest in the center of the universe, while the Earth orbits around the Sun together with the other planets. One could then ask oneself: If the living Earth is not a unique place, why would not then the other planets harbor life too? One of the first to draw the consequences of the Copernican-heliocentric worldview was the Italian Dominican friar and philosopher Giordano Bruno, who supposed that life might exist on planets in other solar systems.

The German astronomer Johannes Kepler, known for his laws of planetary motion, combined the new understanding of the universe with the idea of life on other planets. His posthumous work, *Somnium* (The Dream, 1634), can be said to be the first space voyage story based on scientific theories. The fictional framework let him convey the new astronomical worldview. *Somnium* is about a young Icelander, Duracotus, who travels to Denmark to hand over letters to Tycho Brahe. Later in the story, Duracotus travels in his dreams to the Moon. The weightlessness and the effect of gravity on the body are discussed, as well as the topography of the Moon. Kepler assumes that there is an atmosphere on the Moon and that it has conditions for life. Because the mountains are higher and the valleys deeper on the Moon, the lunar inhabitants are larger than us, have a greater appetite, grow faster, and die earlier. Duracotus meets animals such as large lizards and monsters, and *Somnium* becomes a nightmare, where everything is magnified.

A turning point in the history of astrobiology took place in the autumn of 1609, when the Italian physicist and astronomer Galileo Galilei turned a telescope for the very first time towards the starry sky. He then studied the surface of the Moon, and

it turned out to be a rugged surface with mountains, valleys, and plains. His astonishing discoveries were published in *Sidereus nuncius* (Sidereal Messenger, 1610), which also included the very first images of the Moon seen through a telescope. Furthermore, with the same instrument, he found that the Sun had spots, that Jupiter had four moons, that Venus had phases like the Moon, and that the Milky Way consisted of innumerable stars. In the following decades, these discoveries sparked a debate and speculations concerning the presence of life on other planets. A convinced Copernican, the English natural philosopher John Wilkins, put forward 14 claims confirming the plurality of worlds. In the end he predicts that it is possible that some of our descendants will invent a way to get to this other world, and if there are inhabitants there, they will trade with them. One of Wilkins's critics, the Scottish writer Alexander Ross, answered with a book entitled *The New Planet, No Planet; or, the Earth No Wandering Star Except in the Wandering Heads of Galileans* (1646) (Fig. 1).

Imaginary space voyages commonly follow the narrative of the utopian genre, where the author uses foreign cultures and imaginary worlds in order to put forward a critique of the contemporary society or culture and to express alternative realities and possibilities. The order of things could be in a completely different way than it happens to be. In the middle of the seventeenth century, a number of Moon stories were published. The English author Francis Godwin's novel *The Man in the Moone: or A Discovrse of a Voyage Thither* (1638) tells about Domingo Gonsales, who travelled to the Moon with a

flock of trained wild swans or "gansas." The journey took twelve days. He stayed there a year, encountered the Lunarians, then returned to Earth and landed in China. The novel describes, among other things, the tones of the lunar language, which are reminiscent of the Chinese tonal system and musical cipher. From the same year is John Wilkins' *The Discovery of a World in the Moone* (1638). In *Itinerarium exstaticum* (Ecstatic Itinerary, 1656), by the German Jesuit Athanasius Kircher, the narrator Theodidactus takes a cosmic journey together with an angel as guide and tutor. The French satiric novelist Savinien de Cyrano de Bergerac wrote *L'Autre monde: où Les états et empires de la lune* (The Other World: Comical History of the States and Empires of the Moon, 1657). Cyrano travelled with bottles of dew attached to him which lifted him up with the heat of the Sun, but he eventually returned back to Earth and landed in Canada. A second time, he travelled with rockets to the Moon. He then met the lunar inhabitants, whom he tried to convince that their Moon was our world and was inhabited. In a later story from 1662, Cyrano also travelled to the Sun (Figs. 2 and 3).

The space travel stories were not only the unlimited means of imagination, but many used

the theme, like Kepler, as a way of presenting the new scientific worldview. An influential work, written by the French essayist Bernard Le Bovier de Fontenelle, *Entretiens sur la pluralité des mondes* (Conversations on the Plurality of Worlds, 1686), consists of six evening lectures that take place as a conversation between a philosopher and his aristocratic hostess in the gardens of a country chateau. All philosophy, he says, is based on two things: curiosity and poor eyesight. We want to know more than we can see. During the walks, they discussed the plurality of the worlds and the existence of intelligent beings on other planets. Maybe there is, says the philosopher, astronomers on Jupiter, and maybe we cause them scientific disputes, where some philosophers have to defend their opinion that we exist. The marchioness speculates, since the inhabitants of Venus are closer to the Sun, they might be small black creatures, scorched by the Sun, full of fire, and very amorous. . . (Fig. 4)

The Dutch physicist and astronomer Christiaan Huygens expresses in *Cosmotheoros* (1698) his thoughts on extraterrestrial life and claims that life on other planets would be similar to what we find on Earth. Among other things, he notes that water in liquid form is necessary for life. He also seemed to have detected darker and brighter spots on the surface of Mars and Jupiter, which must, according to him, be understood as water and ice. Beyond our solar system, there are stars of the same kind as our Sun – and why, he wonders,

Imaginary Voyages (from Antiquity to the Eighteenth Century), Fig. 4 An aristocratic lady and a philosopher discuss the plurality of worlds. An edition from 1687 of Bernard Le Bovier de Fontenelle, *Entretiens sur la pluralité des mondes* (1686)

could these not in turn have their planets with their own moons? Huygens's aliens are in many ways like Earthlings, they have mathematics, astronomy, and music, have similar gifts of understanding and moral perceptions.

In the eighteenth century, the idea of life on other planets became widely accepted, and a fashionable topic of discussion among scientists, philosophers, and theologians. The Swedish inventor Christopher Polhem tells in *Nyia tiender uthur månan* (News from the Moon) from the 1710s about a Sami who travels to the Moon. A Sami had been engaged by a couple of learned gentlemen in Uppsala to fly up in the air with the help of wings, but after several failed flight attempts, a Sami magician came up with a different idea of how to get to the Moon. With the help of his magic drum, he was able to travel there. He stayed on the Moon for seven months and meanwhile, learned the language of the lunar inhabitants. When he returned, he told about everything he had seen and heard.

Voyage to Cacklogallinia (1727), written under the pseudonym Samuel Brunt, begins in a land of birds. The story tells about an expedition to the Moon where they collect gold on the mountains of the Moon and take it back to Cacklogallinia. The lunar inhabitants turned out to be idealists and had no material desires. In the Norwegian-Danish author Ludvig Holberg's satirical story *Iter subterraneum* (Underground Journey, 1741), the

space travel goes into the Earth. During a mountain trip in Norway, the hero of the story, Niels Klim, tumbles into a hole and falls to the Earth's interior, which turns out to be hollow containing its own planetary system. After ending up in a circular orbit, he finally lands on the planet Nazar where he finds a land of trees, the Principality of Potu. Everything was different there – like a satire of terrestrial life. He attended dissertation defenses that took place as popular theatrical pleasures. The judgment was considered distorted and bad. It was thought that those who immediately grasped something must necessarily lack power in their judgment. This satirical genre of space travels also includes a story of the French Enlightenment philosopher François Marie Arouet de Voltaire, *Le Micromégas*, published in 1752. It tells about a 120,000-foot-long inhabitant of a planet belonging to Sirius who visits our solar system. He had been deported because he had claimed that there were inhabitants on planets other than his.

A book that stands out is *De telluribus in mundo nostro solari* (The Earths in our Solar System, 1758), written by the Swedish scientist and theologian Emanuel Swedenborg. He explicitly states, without irony, that he himself, on many occasions in the spiritual world, had conversed with beings from other planets. With Martians, Venusians, and inhabitants of planets in other solar systems, he had deep theological and scientific conversations. As a mechanic and scientist, Swedenborg had previously designed the first airplane with fixed wings. Before Kant and Laplace, he had also presented a nebular hypothesis explaining the formation of our solar system and its planets. In the same work, *Principia rerum naturalium* (The Principles of Natural Things, 1734), he also expressed the possibility of life on other planets in other solar systems.

The idea of life on other planets became an imaginative theme for poets and satirists, even plays and operas were written. In Joseph Haydn's opera *Il mondo della Luna* (World of the Moon, 1777), the old man Buonafede is tricked by his daughters' cavaliers into traveling to the Moon where he meets the emperor of the Moon, who causes him to consent to their marriage.

From being an impossibility during the Middle Ages, extraterrestrial life became a possibility at the end of eighteenth century, even a probability based on a new cosmology, new observations, and interpretations. The French Enlightenment philosophers Diderot, d'Alembert, and d'Holbach embraced the idea of the plurality of worlds. The existence of a multitude of worlds with rational beings was also assumed by the German philosopher Immanuel Kant to be very probable. The German-British astronomer William Herschel explained that his conclusion about the existence of other worlds was based on astronomical foundations, not on fantasy, theology, and poetry. He did not doubt that the Moon was inhabited, and in 1776 he even claimed that he had detected growing patterns on the Moon, which he interpreted as forests. "I am," he says two years later, "almost convinced that these numberless small Circuses we see on the Moon are the works of the Lunarians and may be called their Towns."

Overview

What these imaginary space voyages and stories about life on the Moon and other planets capture are questions about truth, how we can know what we know, how we gain knowledge about what we do not know, how we imagine the unknown, and where the limits of the imagination go. In general, it can be said that the conceptions of the unknown always have their beginning in the known. When humans try to think freely, fantasize, and speculate, they are limited by what they already know, their culture and way of life. It is, obviously, difficult to know so much about the unknown. Therefore, human conceptions and imaginations of life in space say a lot about the human being itself, human thinking, knowledge, and dreams.

Imaging

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Keywords

Adaptive optics · CCD · Camera · Direct detection · Telescope

Definition

Imaging is the set of techniques used for obtaining images of one or several astronomical bodies or fields using a two-dimensional detector, computerized techniques, and smart optical techniques such as ► [adaptive optics](#).

Overview

In astronomy, imaging is in most cases the first observational approach to discovering a new object, the image being required to clarify structure and morphology, before using the more physical tool of ► [spectroscopy](#). Shape, size, decomposition into elements, arrangement of subparts, measurement of displacements, and discrimination of photometric variations belong to the set of information provided by the image. From the planets in the solar system to the identification of gigantic filamentary structures or sheets in the universe, the image has played a major role in astronomy. Improving the quality of the image has been and remains today more than ever a powerful drive in instrumental research: two-dimensional detectors, high angular resolution, ► [adaptive optics](#), high dynamical range, and post-processing techniques are fields of intense activity. One notes that the direct detection of exoplanets is certainly among the most demanding topics in terms of angular resolution and high contrast.

Detectors: In the last 40 years, the photographic technique has been largely replaced by digital sensors such as CCDs and now CMOS chips (complementary metal-oxide-semiconductor, a technology used for constructing integrated circuits). Giant cameras associating several tens of CCD chips can feature up to 500 Mpixels and cover extra-large fields on the sky, as demonstrated, for instance, by Megacam, a camera installed at the Canada-France-Hawaii Telescope (Fig. 1). CCDs provide numerical images, which can easily be processed by computers. They also offer a very good detection efficiency in a large domain of wavelength. Beyond $\lambda = 1 \mu\text{m}$, infrared arrays based on the CMOS technique have about the same

Imaging, Fig. 1 The Megacam camera developed by CEA-France and installed at the prime focus of the Canada-France-Hawaii Telescope, behind a wide field corrector. This huge camera includes 36 CCDs of $2,048 \times 4,612$ pixels each, arranged side by side, leading to a total of 340 Mpixels

advantages. Recently large arrays of infrared bolometers have been produced, allowing imaging in even the submillimeter domain.

A certain degree of computer correction for atmospheric and instrumental effects allows sharpening up the image and improving the contrast. Multiple digital images can also be combined to further enhance the signal-to-noise and suppress artifacts. Thanks to the ► [adaptive optics](#) technology that can negate to a large extent the atmospheric blurring, image quality can approach the theoretical resolution capability of the telescope, that is, angular details as small as $\theta = \lambda/D$, where D is the diameter of the telescope and λ the wavelength. For $\lambda = 2 \mu\text{m}$ and a $D = 8 \text{ m}$, this corresponds to a length of 10 km on Venus' surface or the orbit of Mercury seen around a star at 300 light-years. In space, almost perfect conditions also provide excellent angular resolution, despite a more moderate telescope size, as illustrated by the stunning images of the Hubble Space Telescope. The future James Webb Space Telescope with its 6.5 m diameter telescope will soon provide similar exquisite image quality but in the infrared domain.

As regards high contrast imaging, the recent pressure put by the search for exoplanets was the

Imaging, Fig. 2 High-contrast imaging. Thanks to the combination of dedicated optical devices (here a four-quadrant phase mask coronagraph) and imaging techniques (here differential rotation), it is possible to reach an extremely high contrast ratio at the laboratory: a fake *planet* 0.15 billion times fainter than an artificial star (behind the central occulted disk) is perfectly seen on this image obtained at LESIA, Observatoire de Paris

cause of an explosion of ideas and new concepts to mitigate the problem of the huge difference in brightness between a star and the planets orbiting it. New types of coronagraphs to hide the starlight, of wavefront control to reduce speckles, and of pupil shaping to suppress the wings of the point spread function produced by diffraction have been proposed and tested. Also, differential techniques based on chromatic differences, or on image rotation, or on polarization properties have been refined and greatly improve the detection capability. Today in the laboratory, a contrast of 10^{-9} is reached at an angular distance of a few λ/D only (Fig. 2). The past decade has seen those techniques implemented in ground-based or space instruments, such as SPHERE on the ESO-VLT, GPI on Gemini, SCExAO on the Subaru telescope, and on the James Webb space telescope launched late 2021. In the near future, the Nancy-Grace Roman space telescope equipped with a state-of-the-art coronagraph should probably give the highest contrast ever reached in astronomical observation.

Impact Basin

Roland J. Wagner
German Aerospace Center (DLR), Institute of Planetary Research, Berlin, Germany

Definition

An impact basin is a large complex impact crater. The threshold diameter to distinguish between

craters and basins is approximately 150–200 km. In general, basins are characterized by two or more concentric rings, which are ridges or scarps facing toward the basin. One of these rings is the main rim that borders the cavity from which material was excavated and ejected during the impact. Most basins are heavily degraded or have been covered by younger material. All known basins are old impact features created during the first 800 million years of the planet or satellite on which they are found. Examples are Caloris Basin on ► [Mercury](#), the Orientale Basin on the Moon, and the Hellas Basin on ► [Mars](#).

Impact Degassing

Reika Yokochi
Department of Geophysical Sciences, The University of Chicago, Chicago, IL, USA
Department of Earth and Environmental Sciences, University of Illinois at Chicago, Chicago, IL, USA

Keywords

Planetary accretion · Meteor impacts · Formation of planetary atmospheres · Volatile inventory of planets

Synonyms

[Shock devolatilization](#)

Definition

Impact degassing refers to the release of gas caused by a high-velocity collision of volatile-bearing

solid objects, particularly during collisions between planetary objects. During an event or collision, an intense mechanical shock wave is transmitted, causing changes in specific volumes along the material-specific Hugoniot curve (see ► [Spallation Zone](#)). A rarefaction wave subsequently propagates to reduce the shock pressure, during which the kinetic energy of the collision is released as heat and as high particle velocity of the ejecta. The change in thermodynamic conditions causes phase transitions of the material in the colliding objects, either in the solid state or by melting and vaporization, which releases structurally bonded volatiles as well as interstitially trapped gases.

Overview

The discovery of impact craters on the Moon during the Apollo missions first inspired the studies of collisional shock on geological materials. Theoretical studies started by investigating the thermodynamic stabilities of mineral matrices in colliding geological objects that are free of structural volatiles (Ahrens and O’Keeffe 1972; Luo and Ahrens 2004).

In the context of planetary evolution and the formation of planetary atmospheres that may have fostered emergence of life, the main focus of investigation concerns the release of structurally bound major volatiles from hydrous minerals, carbonate, as well as ice. The shock-loading experimental studies demonstrated that structurally bound water in hydrous minerals (Boslough et al. 1980; Lange et al. 1985) could be lost during hypervelocity impacts, whereas theoretical and experimental studies suggest that minerals containing volatile elements as major constituents (i.e., carbonate, sulfate, and H₂O ice) initiate vaporization at relatively low-impact velocity (Shen et al. 2003; Stewart and Ahrens 2005; Ohno et al. 2008). Tyburczy et al. (1986) experimentally investigated shock-induced volatile loss from the Murchison CM2 chondrite and observed that complete devolatilization occurs at a pressure of about 30 GPa, corresponding to ~27 % of Earth’s present mass. This validates that the conclusions based on individual minerals above generally apply when they are embedded with other

minerals in the primitive meteorite, a potential precursor of planets. It is therefore likely that impact degassing from planetary precursor materials played a significant role in directing the surface evolution of planets and the chemical compositions of planetary atmospheres. Recent shock-loading experiments and theoretical studies involve detailed investigation of chemical changes, for example, on hydration of olivine by shock-released water (Furukawa et al. 2011), on the survival or formation of amino acids that have direct implications for life-forming molecules (Pierazzo and Chyba 1999; Sugita and Schultz 2009), or destruction of complex molecules to form chemically simpler constituents of atmospheres (Fukuzaki et al. 2010).

The moon-forming impact caused large-scale melting of the Earth, resulting in a large-scale degassing from the silicate Earth to the atmosphere. Whether this event resulted in significant loss of atmosphere to space and/or chemical and isotopic fractionation of the terrestrial atmosphere remains controversial.

Impact Melt Rock

Philippe Claeys
Earth System Science, Vrije Universiteit Brussel,
Brussels, Belgium

Definition

An *impact melt rock* is a type of rock typically found in impact structures. It is an impactite consisting of a mixture of solid and melt fragments all derived from the target rock, floating in a glassy, microcrystalline, or recrystallized matrix. The solid fragments may contain shocked

minerals, most commonly quartz or zircons. An impact melt rock results from the cooling of the melt pool that formed within a crater, because of the high temperature and pressure generated during the impact. The largest craters on Earth such as Sudbury (Ontario, Canada), Chicxulub (Mexico), Popigai (Siberia), or Manicouagan (Québec, Canada) contain a very large volume of impact melt rocks.

Cross-References

Impact Parameter

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

The impact parameter is the projected distance between the axis carrying the initial vector velocity of a projectile and the center of the target that the projectile is approaching (see Fig. 1).

Impact Parameter,
Fig. 1 Definition of the impact parameter (*dark arrow*) of a projectile directed toward a target

Impact, Hit and Run

Sean N. Raymond
Laboratoire d'Astrophysique de Bordeaux,
CNRS, Université de Bordeaux, Bordeaux,
France

Definition

During terrestrial planet formation, the so-called hit-and-run impacts are giant impacts that do not result in a net increase in the mass of at least one of the planetary embryos involved in the collision. Hit-and-run impacts generally imply high relative velocities between bodies and/or oblique impact angles. In such cases, the larger body does not accrete the smaller body, but the larger object could actually be eroded and sometimes severely traumatized by the encounter. A significant amount of debris may be created in hit-and-run impacts.

Cross-References

- [Giant Impact](#)

Impact, Probability of

J. Andy Spry
SETI Institute, Mountain View, CA, USA

Definition

For purposes of planetary protection, the probability of impact at a target body is the probability, determined by sequential evaluation of possible spacecraft trajectory analyses and failure modes, that a spacecraft might impact a planetary body under nominal and non-nominal conditions. The impact probability for a mission often has a set limit for planetary protection compliance.

Impactite

Philippe Claeys
Analytical-Environmental & Geo-Chemistry,
Vrije Universiteit Brussel, Brussels, Belgium

Definition

Impactite is a term used to describe rocks formed during a meteorite impact on a planetary body. The term covers the lithologies such as breccia, suevite, or impact melt rock found within or at proximity of an impact structure. Monomictic breccias contain fragments of a single rock type; polymictic breccias contain several rock types originating from the target lithologies. Each is composed of chaotic assemblages of solid and shocked fragments, or previously molten fragments, of the target lithologies. Suevite is a breccia containing melt and solid particles surrounded by a fine clastic matrix, first defined in the Ries crater (Germany). Distal impactite, composed of fine ejected material (spherules, shocked minerals), may be widespread in the case of large impacts such as the one that formed the Chicxulub crater, in Yucatan (Mexico), 66 million years ago.

Infrared Astronomical Satellite

José Cernicharo Quintanilla
Laboratory of Molecular Astrophysics,
IFF-CSIC, Madrid, Spain

Synonyms

[IRAS](#)

Definition

The Infrared Astronomical Satellite or IRAS was the first observatory to perform an all-sky survey at infrared wavelengths. It was equipped with a telescope of 60 cm diameter and with detectors operating at wavelengths of 12, 25, 60, and 100 μm with angular resolution of 30 arc sec and 2 arc min at 12 and 100 μm , respectively. Launched on January 25, 1983, it was operating up to November 21, 1983. During its primary mission, which was to obtain a complete map of the sky, it discovered 350,000 point-like sources, increasing the number of cataloged astronomical sources by about 70%. IRAS discoveries included a disk of dust grains around the star Vega, six new comets, and very strong infrared emission from interacting galaxies, as well as wisps of warm dust called infrared cirrus which are found in almost every direction of space. IRAS also revealed for the first time the core of our galaxy, the Milky Way. In addition to the infrared sky maps, IRAS was also equipped with a low-resolution spectrometer that was used to observe thousands of objects in the mid-infrared. The outstanding scientific results obtained by IRAS opened a new view of the universe and motivated new infrared space facilities such as ISO, Spitzer, and Herschel.

History

The project was initiated in 1975 as a joint program of the USA, the Netherlands, and the UK. Launched in January 1983, it produced infrared data for a period of 10 months and covered more than 96% of the sky.

Infrared Astronomy

Daniel Rouan
 LESIA, Observatoire Paris-Site de Meudon,
 Meudon, France

Synonyms

[Far infrared \(far IR\)](#); [Near infrared \(near IR\)](#)

Definition

Infrared astronomy is the branch of observational astronomy which studies celestial objects through their infrared radiation, that is, at wavelengths longer than 0.75 μm and shorter than 400 μm . The domain is not strictly defined, and some astronomers consider that it begins at 1 μm where ► [CCDs](#), the most universally used detectors in the visible domain, are no longer sensitive. Infrared astronomy is considered as part of *optical astronomy* because technologies and methods (incoherent detection, classical optics, solid-state digital detectors) are globally the same as in the visible domain. One peculiarity of infrared astronomy is the strong ► [background](#) emission of the environment (atmosphere, telescope) that requires dedicated differential techniques. Another one is the absorption by the atmosphere (see Fig. 1) in a large fraction of the wavelength domain: this explains why balloons, airplanes, and satellites are often used to carry instruments. ► [IRAS](#), ISO, and ► [Spitzer](#) are the space instruments that brought the most spectacular results in the field. Main targets in infrared astronomy are *cold* objects such as cool stars (► [brown dwarves](#), M dwarves), ► [interstellar dust](#), planets of the solar system, and now exoplanets.

Infrared Astronomy, Fig. 1 Transmission of the atmosphere in the infrared range. The Earth's atmosphere absorbs the infrared light in the largest part of the wavelength domain: only in a few windows is the transmission good enough to allow observations from the

ground, particularly with telescopes on the top of high mountains (Mauna Kea is a summit at 4200 m on the island of Hawaii, the best infrared site today). At higher altitudes (aircraft, balloon), the conditions are improving and broader windows are open

The infrared domain is of special importance to study planets, since it's where ► [thermal emission](#) peaks and molecules exhibit many spectral features corresponding to transitions between ro-vibrational levels of energy. ► [Infrared spectroscopy](#) is the major tool to study the planetary atmosphere and surface.

Note that the infrared range is generally subdivided into three domains: near infrared (near iR), $\lambda = 1\text{--}5\ \mu\text{m}$; mid-infrared (mid-IR), $\lambda = 5\text{--}25\ \mu\text{m}$; and far infrared (far IR), $\lambda > 25\ \mu\text{m}$.

Infrared Dark Cloud

Nicolas Peretto
School of Physics & Astronomy, Cardiff
University, Cardiff, UK

Keywords

Mid-infrared extinction · Early phases of star formation · Stellar cluster formation · High-mass star formation

Acronyms

IRDC

Definition

An Infrared dark cloud (IRDC) is a large concentration of ► [interstellar dust](#) and gas that is seen in absorption against a bright infrared background. They often correspond to the densest regions of large ► [molecular clouds](#), and as such, IRDCs are often associated with star formation activity. The infrared extinction towards an IRDC is due to the absorption of the background light by the cold dust embedded within it. IRDCs are best observed in the mid-infrared part of the ► [electromagnetic spectrum](#), typically around 10 micron, where the contrast between the emission of the diffuse ► [interstellar medium](#) (i.e., the background emission) and that of the IRDC dust is maximal. This is a direct consequence of the bright broadband mid-infrared emission of ► [polycyclic aromatic hydrocarbons](#) that pervade the interstellar medium (ISM), along with the cold temperature ($\sim 15\ \text{K}$) of dust embedded within IRDCs. IRDCs are observationally defined entities, they have no physical definition attached to their names. As a result, they can be extremely massive and large (tens of parsec, tens of thousands solar masses) or small and compact (tenths of parsecs, a few solar masses), host the formation of a very rich ► [stellar cluster](#) or of a single stellar system.

History

Water vapor efficiently absorbs infrared light. As such, Earth's atmosphere is virtually opaque in the infrared, which makes infrared observations of the diffuse ISM extremely difficult. It is only with the launch of the first space observatories, from the mid-eighties to the mid-nineties, that the first infrared images of the diffuse ISM were taken, and with those the first images of IRDCs. In fact, they were first observed with the ► [Infrared Space Observatory](#) (ISO, Perault et al. 1996), quickly followed by the Midcourse Space Experiment (MSX, Egan et al. 1998). Very early after their discovery, IRDCs attracted a lot of attention due to their possible association with the early phases of massive star formation. The first complete catalogue of galactic plane IRDCs was published in 2006 using the MSX data (Simon et al. 2006a), followed three years later by its ► [Spitzer Space Telescope](#) equivalent (Peretto and Fuller 2009), each containing more than 11,000 entries. IRDCs identified in the 8 micron

Spitzer images were then named Spitzer Dark Clouds (SDCs) (Fig. 1).

Overview

Even though IRDCs can be located anywhere in the sky where the conditions of cold dust and bright infrared background are met, most IRDC literature refers to Galactic plane IRDCs located at a typical heliocentric distance of 5 ± 3 kpc (e.g., Simon et al. 2006b). One advantage of IRDCs compared to other clouds located in the solar circle is that their near/far distance ambiguity is reduced, with IRDCs being most often located at the near heliocentric distance (Ellsworth-Bowers et al. 2013). Reduced distance uncertainties mean more reliable size, mass, and luminosity estimates, which is a very important aspect of IRDC research.

The study of IRDCs is most often associated to that of the early phases of star formation. The cold and dense gas conditions necessary to

Infrared Dark Cloud, Fig. 1 Example of an infrared dark cloud. On the left we have a mid-infrared three colour image of the SDC13 infrared dark cloud (Peretto et al. 2014). Blue and green are the Spitzer 3.6 micron and 8micron emission, respectively, red is the Herschel 70micron emission. The IRDC here is a typical hub, with a set of dark converging filaments seen in absorption. In the middle we see the same SDC13 IRDC, but this time the H_2 column density, derived from ammonia emission, is displayed (Williams et al. 2018). One can see that the

IRDC filaments appear as the densest interstellar structures there is in the field. Local peaks in this image show the fragmentation of the filaments into individual cores that will form stars in the near future. On the right, one can see the centroid velocity map of SDC13 as derived from ammonia emission line. One can see that the IRDC shows important velocity gradients that are interpreted as flows of matter driven by self-gravity (Williams et al. 2018)

produce mid-infrared extinction are those required for the gas to collapse and fragment into individual prestellar cores, that is, the direct progenitors of individual stars or small stellar systems. After the collapse of these cores, protostars start to form and heat up the surrounding dust which then starts to emit in the infrared. IRDCs become therefore less infrared dark as star formation proceeds. As a consequence, studies of IRDCs are often aimed at determining the initial conditions of star formation, before that feedback from newly formed stars perturbs the physical properties of the gas.

One important aspect of IRDC research has focused on determining the initial conditions of ► [high mass star](#) formation, in particular searching for massive prestellar cores. The existence of these objects is predicted by one of the most influential theories of massive star formation that postulates that the formation of massive stars begins within a compact, massive, and initially stable prestellar core (McKee and Tan 2003). The observation of massive prestellar cores would provide a clear-cut test against competing theories (e.g., Vázquez-Semadeni et al. 2019). Massive IRDCs represent the ideal playground for the hunt of massive prestellar cores.

Another aspect of IRDC research that has received significant attention in the past few years is related to hub filamentary systems (Myers 2009). These structures are dense star-forming clouds that exhibit a small network of converging ► [interstellar filaments](#) (Fig. 1). In IRDCs, hubs are easy to spot thanks to the high sensitivity and high angular resolution of infrared extinction mapping. The interest generated by these structures comes from their morphology, suggestive of filament-filament interactions and gravitational collapse, a process that could help the formation of massive stars.

But IRDC research is not limited to the search for massive prestellar cores and characterization of hub filamentary systems. In fact, all aspects of star formation research are being tackled via the study of IRDCs (fragmentation, kinematics, chemistry, magnetic fields, protostellar population, etc...), and their ubiquity across the

► [Milky Way](#) makes statistical analysis of star-forming cloud properties possible.

Basic Methodology

IRDCs are, by definition, first identified as extinction features in ► [continuum](#)-infrared images, typically at around 10 micron (note that they can also be identified at shorter and longer infrared wavelengths). The amount of observed extinction towards the IRDC is a measure of the cloud dust ► [opacity](#) τ which in turn is directly proportional to the mass surface density, or ► [column density](#), of dust and gas. Therefore, by making some assumptions on the emission properties of the IRDC foreground and background dust one can reconstruct the mass surface density structure of any IRDCs, and this independently of the dust temperature (see Peretto and Fuller 2009). Another advantage of extinction mapping is that it typically provides high-angular resolution observations (i.e., $\sim 2''$ with Spitzer at 8 micron).

While infrared extinction is very powerful to recover the structure of infrared dark clouds, it has its own limitations. First, if young stellar objects are present within the IRDC, then these will appear as holes in the reconstructed mass surface density image of the cloud. Second, the foreground and background intensities of a cloud are rather poorly constrained, leading to large uncertainties on the opacities. Finally, infrared extinction can only inform of the mass surface density of the IRDC, and nothing else.

The low dust and gas temperatures in IRDCs, as in any molecular cloud, are such that most of the thermal energy they radiate is at (sub)-millimeter wavelengths (>100 micron). At these wavelengths, thermal dust continuum emission is optically thin up to mass surface densities ~ 100 g/cm² and is therefore an excellent tracer of dust mass for most IRDCs, whose average surface density is typically ~ 0.1 g/cm². In this optically thin regime, IRDC dust masses are proportional to their (sub)-millimeter flux, while gas masses are usually derived by assuming a constant dust-to-gas mass ratio of $R_{dg} = 1\%$ (see Hildebrand 1983).

In IRDCs, molecular line emission mostly corresponds to rotational transitions, the only transitions that can easily be collisionally excited in a ~ 15 K gas. More than 200 ► [interstellar molecules](#) have been identified so far (McGuire et al. 2018), but the combination of abundance and excitation conditions determines which ones are observable in a given region of a molecular cloud. For instance, ► [carbon monoxide](#) is the second most abundant molecule in space and is very easily observed towards molecular clouds. However, in ► [dense clouds](#) such as IRDCs, the low energy transitions of CO tend to be optically thick and are therefore of no use when, for instance, one tries to determine IRDC dynamics. In order to map the kinematics of the gas within IRDCs, optically thinner transitions are used, such as those of ► [diazenylium](#) (N_2H^+) or ► [ammonia](#) (NH_3). The width of the emission line gives access to the velocity dispersion of the gas along the line of sight, the peak velocity gives access to the centroid velocity along the line of sight, the peak intensity can give information on the excitation temperature, and the integrated line intensities provide some information on the column density of the molecule and abundance if the total column density of molecular hydrogen, the most abundant molecule in space, is known.

Finally, for the detection of young stellar objects, infrared dust continuum emission and non-thermal radio emission (cm to m wavelengths) can trace dust heated up by the newly formed stars or gas that has been ionized by them, respectively. The latter mostly happens to young massive stars that are hot enough to produce ionizing ultraviolet photons, resulting in the formation of ► [HII regions](#).

Key Research Findings

Soon after their discovery in the late nineties, a number of studies aimed at characterizing the properties of IRDCs and identifying the role they play in the star formation process. The first studies aimed at determining what was the relation between IRDCs and some of the better known interstellar

structures. In that respect, Teyssier et al. (2002), by observing emission from CO isotopologues towards a sample of IRDCs, showed that they were in fact nothing else than some of the densest regions within Galactic plane molecular clouds. Since then, plethora of dust continuum observations have shown that IRDCs have the correct temperature, mass, and fragmentation properties to be the progenitors of stellar clusters (e.g., Rathborne et al. 2006; Pillai et al. 2006; Peretto and Fuller 2010; Ragan et al. 2011; Battersby et al. 2011; Zhang et al. 2015). IRDCs also often show signs of star formation activity (e.g., Chambers et al. 2009; Peretto and Fuller 2009), highlighting the fact that star formation, even though at an early stage, has already started. In some cases, even evidence of ongoing massive star formation has been found (Rathborne et al. 2005; Pillai et al. 2011, and Wang et al. 2012). In fact, one of the most massive cores ever observed in the Galaxy lies right at the center of an IRDC (Peretto et al. 2013). This discovery shows that the formation of massive cores can occur early on during the evolution of a molecular cloud. But despite intense scrutiny of IRDCs with some of the most powerful millimeter telescopes in the world such as ► [ALMA](#), no significant population of massive starless cores has been found (Svoboda et al. 2019; Sanhueza et al. 2019). All massive cores that exist out there seem to be protostellar in nature.

The question of what physical mechanism drives the fragmentation of IRDCs into cores and how these then evolve is one of the key areas of star formation research. It has been suggested that, at least for filamentary IRDCs, the fragmentation scale is set by the average mass-per-unit-length of the cloud on a large scale, while it is the local density and the thermal Jeans length that determines core separation on small scales (Kainulainen et al. 2013). However, once formed, cores may simultaneously collapse to form protostars and accrete more mass via the collapse of the IRDC itself (Peretto et al. 2020; Rigby et al. 2021). This would naturally explain the absence of massive prestellar cores. The accretion from the IRDC to the cores may occur via filament accretion channels (i.e., hubs) that converge towards the massive ► [protostars](#) at the

center (e.g., Peretto et al. 2014; Williams et al. 2018). When computing the mass distribution of the starless IRDC fragments/cores, one finds that it is much steeper than that of the IRDCs themselves, highlighting in fact the different nature of the process leading to the early fragmentation of IRDCs to that of the formation of IRDCs (Peretto and Fuller 2010). When including protostellar sources, the core mass distribution within IRDCs becomes, at least in the case of one IRDC, flatter than those found in nearby star-forming regions, suggesting that, in the process of star cluster formation, low-mass stars form after high-mass stars (Zhang et al. 2015). This is reminiscent of what Motte et al. (2018) found in the W43-MM1 massive-star forming region, but more studies on the core mass distribution of IRDCs, and how cores are linked to local accretion channels, are necessary in order to determine the importance of such results.

Future Directions

IRDCs, because of their nature and large numbers across the Galactic plane, are great laboratories for the study of the earliest stages of star cluster formation. However, follow-up surveys of IRDCs have so far been limited to small sample sizes of, at best, a few tens of objects. Future large observing programs surveying hundreds of IRDCs, at high angular resolution and across a broad range of spatial scales, will provide enough statistics on the fragmentation and internal IRDC gas kinematics to draw robust conclusions on the physical mechanisms that are at play during the early phases of star formation.

Infrared Excess

Steven W. Stahler

Department of Astronomy, University of California, Berkeley, CA, USA

Keywords

Interstellar dust

Definition

Many ► [pre-main sequence](#) stars emit substantial amounts of energy at infrared and longer wavelengths. To the degree that the flux at each wavelength exceeds the corresponding blackbody value (corresponding to the temperature of the stellar photosphere), the star is said to have an infrared excess. At least half of T Tauri stars have infrared excesses. Much of this emission arises from heated dust grains embedded in circumstellar disks. Other T Tauri stars have no infrared excess. Presumably, these stars have no disks, although they are of similar age. All stars must lose their disks by the time they reach the ► [main sequence](#), whose stars do not have an infrared excess.

Overview

Stars radiate over a broad range of wavelengths. A plot of radiation intensity as a function of wavelength, when covering a substantial range in the latter, is known as a spectral energy distribution. In such a plot, each intensity is measured using a relatively broad filter, which admits radiation over a wavelength range of roughly 1000 Å (100 nm).

A main sequence star radiates like a blackbody. That is, its spectral energy distribution resembles, at least approximately, the Planck curve corresponding to the star's surface temperature. The spectral energy distributions of young stars, however, depart sharply from the Planck curve. These objects are often surrounded by considerable amounts of interstellar dust, which absorbs and reddens the radiation in a wavelength-dependent manner. The raw intensities must

therefore be corrected, a procedure known as dereddening.

Even after dereddening, many T Tauri stars exhibit substantial flux above a blackbody at infrared and longer wavelengths. In these so-called classical T Tauri stars, the total excess flux emitted in the infrared can be a substantial fraction of the total stellar luminosity. Other T Tauri stars, the so-called weak-lined class, have no such excess.

T Tauri stars are pre-main sequence objects of roughly solar mass and below. That is, they are contracting slowly and generating energy through that contraction, but not yet capable of fusing hydrogen into helium. Detailed analysis of the infrared excess emission from classical T Tauri stars shows that it arises from radiation by heated dust grains. These grains must be relatively close to the star. Most are embedded in circumstellar disks, which have been imaged directly in some cases. It is surprising that weak-lined T Tauri stars, which have similar ages as the classical ones, apparently lack these disks.

Pre-main sequence objects of larger mass, from about 2 to 10 solar masses, are known as Herbig Ae and Be stars. Many of these also exhibit large infrared excesses. There are also many stars, presumably of lower mass, which are so deeply embedded in dust that all their emission is at infrared and longer wavelengths. Some of these latter sources are believed to be true protostars, objects deriving their luminosity from the infall of cloud material onto the stellar surface.

ISO

Definition

The Infrared Space Observatory (ISO), a project of the European Space Agency (ESA) with the participation of ► [NASA](#) and ISAS (now ► [JAXA](#)), was the first cryogenic spaceborne infrared observatory for astronomy. It operated from 1995 to 1998 and made detailed imaging, photometric and spectroscopic observations at wavelengths from 2 to 200 μm of all kinds of astronomical objects from planets and comets in our own Solar System right out to distant extragalactic sources. Its contributions to astrobiology include the detection in space of water, complex organic molecules, and a rich variety of ices (Fig. 1).

Overview

The Infrared Space Observatory (ISO), selected by ESA in 1983, made a detailed exploration of the infrared universe. Industrial design and development started in 1986 with Aérospatiale (now Thales Cannes) as prime contractor. An Ariane 44P vehicle launched ISO in November 1995, and it operated until May 1998 in an elliptical 24-h orbit with perigee/apogee of 1000/70,000 km. ISO's *Payload Module* was essentially a large cryostat, containing 2300 l of superfluid liquid helium, cooling four scientific

Infrared Space Observatory,

Fig. 1 Schematic of ISO

instruments and a telescope of Ritchey-Chrétien design with a 60 cm diameter primary mirror to temperatures of 2–4 K. The two spectrometers (short-wavelength spectrometer [SWS], long-wavelength spectrometer [LWS]), a camera (ISOCAM), and an imaging photopolarimeter (ISOPHOT) jointly covered wavelengths of 2.5–240 μm with spatial resolutions ranging from 1.5 to 90 arc s, depending on wavelength. The *Service Module* provided the traditional spacecraft services including three-axis attitude stabilization at the arc second level (Kessler et al. 1996).

The mission was a technical, operational, and scientific success with most satellite systems operating far better than specifications and with its scientific results impacting practically all fields of astronomy.

During its 29-month operational lifetime, ISO made over 30,000 individual observations. These data are publically available from the ESA archives (“archives.esac.esa.int” and then click on ISO).

ISO’s scientific legacy is summarized in various overviews and compilations (e.g., First ISO Results 1996; Cox and Kessler 1999; Cesarsky and Salama 2005). The mission made several significant contributions to astrobiology. ISO found water everywhere in the universe – in

comets, ► Mars, the four giant planets and ► Titan, the interstellar medium (toward proto-stars and molecular clouds), evolved stars (both oxygen and carbon rich), and galaxies (e.g., Cernicharo and Crovisier 2005; Encrenaz 2008). ISO’s wide and uninterrupted wavelength coverage, free of telluric contamination, permitted it to make a detailed inventory of interstellar ices (including not only the ubiquitous CO_2 but also $^{13}\text{CO}_2$, CO , H_2O , H_2CO , CH_4 , CH_3OH , CH_3 , OCS , etc.) and gas phase organic molecules (including H_2O , CH_4 , C_2H_2 , CH_3 , HCN , CO_2 , OH , etc.) as well as addressing the rich variety of polycyclic aromatic hydrocarbon features and making an inventory of the reservoirs of the major elements (C, O, N, etc.) (e.g., Ehrenfreund and Charnley 2000; van Dishoeck 2004). In brief, ISO showed conclusively that space is full of the building blocks of life.

Definition

Infrared spectroscopy is spectroscopy using infrared light (0.7–1000 μm ; $\sim 14,000$ – 10 cm^{-1}). Most molecular bonds are characterized by the absorption of specific frequencies of infrared radiation. The 0.7–2.5 μm ($\sim 14,000$ – 4000 cm^{-1}) region is often called the near-infrared, the 2.5–25 μm (4000 – 400 cm^{-1}) region is called the mid-infrared, and the 25–1000 μm (400 – 10 cm^{-1}) region is called the far-infrared.

Overview

Many organic and inorganic materials absorb unique frequencies of infrared light. The absorption is caused by vibrations or rotations of molecules, at frequencies corresponding to the infrared region of the electromagnetic spectrum. Therefore, information about molecular species and structure can be obtained by irradiating samples in the infrared frequency range and subsequently

observing the absorption spectra or by observing the corresponding emission spectra if the intensities exceed that of the background radiation. Vibrational transitions in the infrared for some typical functional groups occur in the regions of ~ 3600 – 2500 cm^{-1} (OH stretching), ~ 3100 – 2800 cm^{-1} (CH stretching), ~ 1800 – 1650 cm^{-1} (C=O stretching), and $\sim 1600\text{ cm}^{-1}$ (aromatic C=C stretching) (Socrates 2001).

In the case of transmission infrared spectroscopy, the spectral intensity is usually reported as a transmittance (T) or absorbance (A). The transmittance is defined as the ratio of infrared energy passing through a sample (I) and irradiated infrared energy (background; I_0):

$$T = I/I_0,$$

which is usually shown in % transmittance (% T).

The absorbance is defined as

$$A = -\log_{10} T = -\log_{10}(I/I_0).$$

The absorbance is linearly correlated with the concentration of the component of interest, a relation known as the Lambert-Beer law:

$$A = \varepsilon dC,$$

where ε is the molar absorptivity, d is the thickness of the sample, and C is the concentration of the component of interest. The infrared absorption intensity (or integral absorption intensity), with appropriate baseline correction, can be therefore used for quantitative analyses.

Today, Fourier transform infrared spectroscopy (FTIR) is more commonly used than traditional monochromatic infrared spectroscopy. The instrumentation of FTIR usually consists of a light source, an interferometer (instead of a monochromator), a detector, and a computer system. In FTIR, the time domain spectrum (interferogram) obtained by infrared light passing thorough an interferometer is converted to the frequency-domain spectrum by a Fourier transform. A microscope is often combined with an FTIR for micro-to-millimeter-sized samples and is useful for spatial characterization. Most recently, a

synchrotron radiation light source has been used instead of a conventional ceramic light source. The greater brightness of a synchrotron source enables a better spatial resolution (close to the expected diffraction limit according to the wavelength) and a higher signal-to-noise ratio than ceramic light sources (Holman and Martin 2006). Nanoscale infrared spectroscopy combined with atomic force microscopy (AFM-IR) has been developed to overcome the limitation of spatial resolution due to the diffraction limit (approximately the same as the wavelength) (Dazzi et al. 2012).

Infrared spectroscopy can be applied to solid, liquid, and gas samples. Reflectance methods, such as diffuse reflectance and attenuated total reflection (ATR), are also used particularly for samples not suitable for transmission IR (e.g., thick samples). Infrared spectroscopy is used in astronomical observations of the solar system and the ► [interstellar medium](#), e.g., for identifying constituents of planetary atmospheres and surfaces, and the constituents of ► [molecular clouds](#) in the Milky Way and external galaxies.

Ingenuity

Michel Viso
Innovaxiom, Paris, CX, France

Definition

Ingenuity is the name of a helicopter which was dropped off on the Martian surface (April 4, 2021) by the rover ► [Perseverance](#) about 2 months after its soft landing. The small helicopter (Balaram et al. 2021), with a height of 0.49 m, a mass of 1.8 kg, has a small solar panel on top of two 1.2-meter-wide, two-blade contra-rotating rotors. The energy from the solar panel is stored in rechargeable Li-ion batteries. Ingenuity is equipped with 2 Commercial Off The Shelf (COTS) cameras. A black and white camera looking downward is a navigation camera mandatory to give, in flight, information to the onboard computer. The color camera is designed to take images to be transmitted to Earth and is not needed to fly. In addition to the radio transmitter to communicate with the rover, Ingenuity is equipped with several COTS sensors like an inclinometer, an inertial measurement unit, an altimeter ...

Ingenuity was designed as a technological demonstrator to prove the powered flight in ultra-thin atmosphere, to demonstrate miniaturized flying systems, and to validate autonomous navigation and operation of the helicopter. The technological demonstration phase has lasted up to May 7, 2021, and cumulated about 395 s of flight in five flights.

Then Ingenuity entered operations demonstration phase to help in the design of the travel of Perseverance while the rover is searching the right spots to study and sample. The rough nominal autonomy of the helicopter is 90s. As of the

beginning of 2022, the longest single flight reached 625 m and the highest height it flew was 12 m above the ground. The planned mission lifetime of Ingenuity was 30 days on ► [Mars](#). On September 2021, Ingenuity was granted with an indefinite mission extension by NASA.

Initial Mass Function

Leticia Carigi

[IMF](#)

Definition

The initial mass function describes the relative number of stars, as a function of their individual initial mass m , that forms during a single star-forming episode. It is generally expressed as the number n of stars per unit volume of space per logarithmic initial-stellar-mass interval $d \log m$, $\text{IMF} = dn/d \log m$.

Overview

The IMF is defined over a large interval of masses, from the most massive stars to the lowest mass stars, created in a single star formation burst. It is known that Nature tends to form much more low-mass stars than high-mass stars. For instance, Chabrier (2003) predicts approximately 4000 stars of $1 M_{\odot}$ and 40 stars of $10 M_{\odot}$ for each star of $100 M_{\odot}$.

The initial mass function is often expressed as a multi-segment power law, $\text{IMF} = \text{constant} \times m^{-\alpha}$, for different mass intervals, where α is the slope of the logarithmic plot. In some ranges, a log-normal law is preferred.

The majority of the empirical IMFs has been inferred from star counts observed in the solar neighborhood. This region has had a long history of star formation bursts, including stars of different ages. Hence, to determine the true IMF, it is necessary to correct the actual count, assuming how the star formation rate has changed over time, stellar ages, the number of binary or multiple stellar systems, the Galactic age, and some other factors.

The first and still most popular IMF is that obtained by Salpeter (1955), with slope $\alpha = 2.35$, over the entire unique mass interval between 0.4 and $10 M_{\odot}$. It is important to mention that the astronomical community has often extrapolated it without careful consideration. When Salpeter's IMF is extrapolated to $m < 0.4 M_{\odot}$, the number of very low-mass stars is one or two orders of magnitude larger than the observed value.

In the literature, there are many different IMFs (see Kroupa et al. 2013 and references therein), generally with several slope values for different mass intervals. The dependence of the slope on density and metallicity is well established for the range of massive stars. The disagreement between them is larger for the very low-mass stars, due to their intrinsically low luminosity, and for very massive stars, due to their low stellar lifetime.

From the theoretical point of view, simulations of compressible turbulence, in particular in super-Alfvénic conditions, reproduce qualitatively and

reasonably quantitatively the determined IMF, while the Jeans-type mechanism, with fragmentation due only to gravity, does not (see Chabrier, ► [“Initial Mass Function, Origin of”](#) and references therein).

It is very important to note that the universality of IMF remains as an unsolved problem; however, some recent observations and simulations lean towards an environment and time-dependent IMF through the evolution of the metallicity and the star formation rate (Jeřábková et al. 2018). Moreover, when the number of stars is low, the IMF is not a continuous function and it should be sampled stochastically.

Since stellar properties mainly depend on their initial masses, the IMF is fundamental to the chemical and spectral evolution of star clusters and galaxies.

Star formation

Overview

It was first recognized by Richard Larson in 1981 that ► [molecular clouds](#) are dominated at large scales by strong turbulent motions. ► [Turbulence](#) thus determines the structure of all density regimes in the interstellar gas and in star-forming molecular clouds (MacLow and Klessen 2004). The sources of this turbulence are multiple and can be due to convergent flows in the interstellar medium, supernova explosions, galactic shear, or even more simply to star formation itself. Given the low density of the medium, the turbulent flow is highly compressible and cascades from large to small scales by shock waves. Typical Mach numbers of this turbulence in star-forming molecular clouds range from about 3–8 under usual Milky Way-like conditions, although more extreme values can be found in starburst environments. Observations show a power law dependence between the typical turbulent velocity dispersion, σ , in molecular clouds and the size of the cloud, L , a relation known as one of the Larson’s relations, $\sigma \propto L^\eta$ (see Hennebelle and Falgarone 2013 for a recent review). The power index of this relation, η , is in fact tightly connected to the index of the turbulence velocity power spectrum, n , with $\eta = (n-3)/2$ (e.g., Hennebelle and Chabrier 2008). Numerical simulations of compressible turbulence show that this index is of the order of $n \sim 3.8$, in three dimensions (Beresnyak et al. 2005; Kritsuk et al. 2007), typically between the Kolmogorov value $n = 5/3$ for incompressible turbulence and the Burgers

value $n = 4$ for shock-dominated turbulence. As discussed below, this index plays a key role in the determination of the slope of the ► [initial mass function](#) (IMF).

Key Research Findings

The statistics of the gas density fluctuations created by turbulence is captured by the so-called probability density function (PDF). A key property of turbulence is that in good approximation, the PDF of the *logarithm* of the density ($\log \rho$) is Gaussian, implying that the PDF is lognormal. Such a distribution is expected from the application of the central limit theorem to a hierarchical density field generated by multiplicative processes, such as shocks (Vázquez-Semadeni 1994). Such a lognormal behavior for density fluctuations has received both observational and numerical support. Observationally, the 3D lognormal shape of the PDF is reflected by the projected (2D) power spectrum column density of molecular clouds, measured from dust extinction maps (Kainulainen et al. 2009; Lombardi et al. 2010; Brunt et al. 2010). On the other hand, various numerical simulations of compressible turbulence do show the emergence of a lognormal form for the PDF, at least for the aforementioned typical Mach values, both in supersonic hydrodynamic (e.g., Padoan and Nordlund 2002; Federrath et al. 2010; Schmidt et al. 2010) and MHD turbulence (Lemaster and Stone 2008; Price et al. 2011). Although departure from such a lognormal form does occur under some circumstances, due to the intermittency of turbulence or the nonisothermality of the gas, it remains a reasonable approximation for the aforementioned typical Mach values.

Interestingly enough, observational determinations of the stellar initial mass function, defined originally as the number of stars per logarithmic mass interval, $dN/d\log M$, in various Galactic environments, in the field, in young clusters, and in star-forming regions, confirm that the IMF exhibits a power law tail for masses above about a solar mass, the well-known Salpeter IMF (Salpeter 1955), but

rolls over below about 0.8 solar masses. The IMF is globally well described by a combination of this power law tail and a lognormal form, extending well into the brown dwarf regime (Chabrier 2003, 2005). Most interestingly, the observations of gravitationally bound prestellar cores in various star-forming regions, as revealed in particular by the Herschel satellite (André et al. 2010), called the core mass function (CMF), precursor of the stellar IMF, displays as well a Salpeter power law tail turning down to a lognormal shape at low masses, closely resembling the Chabrier IMF. All these numerical experiments and observations thus strongly suggest that star formation and turbulence are closely linked and that the IMF is imprinted by turbulence in the cloud at the very early stages of the star formation process.

Theory of the Stellar Initial Mass Function

Several attempts have been made to develop a theory linking turbulence and the origin of the IMF. The first attempt to demonstrate the link between the lognormal form of the turbulence PDF and the distribution of Jeans unstable prestellar cores was made by Padoan and Nordlund (2002). Although indeed illustrating the relationship between these two quantities, this theory, however, is based on several ad hoc assumptions and cannot properly reproduce the Salpeter slope of the IMF in the pure hydrodynamic case (without magnetic field), in contrast to what is obtained in numerical simulations. Later on, Hennebelle and Chabrier (2008, 2009), using the analogy between cosmological and turbulence Gaussian density fluctuations, have extended the formalism of Press and Schechter (1974), originally developed to determine the mass function of collapsing dark halos in the primordial universe, to the star formation process. In that case, however, the random field of density fluctuations is no longer uniform, as for the primordial universe, but lognormal, as mentioned above. Combining this distribution of initial density fluctuations with the

virial condition for gravitational collapse, which states that only fluctuations within which gravity dominates over all other sources of support are gravitationally unstable, this theory reproduces all of the key features of the observed CMF and, by extrapolation, of the stellar IMF, including the mass distribution of brown dwarfs, for appropriate density and Mach number conditions. In this theory, the impact of turbulence is twofold. First of all, turbulence-induced shocks lead to a field of overdensities, and fluctuations of the underlying velocity field follow a Kolmogorov-like scale dependence. Fluctuations dense enough to become gravitationally unstable provide the seeds for the future collapsing prestellar cores, including pre-brown dwarf cores at very small scales. The more powerful the turbulence, i.e., the higher the large-scale typical Mach number, the larger the number of small-scale overdensities, thus, of low-mass cores. On the other hand, turbulence constantly sweeps away gas reservoirs which, otherwise, would become Jeans unstable and collapse. As a consequence, mass reservoirs can grow much larger than in the absence of turbulent motions, until eventually they exceed a mass defined as the turbulent, as opposed to purely thermal, Jeans mass. In other words, overdense regions with lower masses than the turbulent Jeans mass will be dispersed back into the flow under the action of turbulence within a turbulent crossing time, before they become dominated by gravity. Only in regions exceeding the turbulent Jeans mass will gravity take over, yielding the collapse of the corresponding mass reservoirs, providing the initial seeds for the massive gravitationally bound prestellar cores.

In this theory, this often called “turbulent support” should thus not be confused with a static support, equivalent to a pressure, but should rather be seen as a random process selecting *at the very early stages of the star formation process* the pieces of gas that will be dominated by gravity and will thus collapse, from the ones that will be dispersed. Eventually, turbulence will of course quickly dissipate, and by the time they are observed, the bound cores will exhibit only thermal inner motions, but turbulence will have been the initial triggering mechanism. This key role of turbulent motions,

characterized by the velocity power spectrum index mentioned previously, is mandatory to obtain the proper Salpeter slope at high masses for the IMF, the slope being directly related to this index (Hennebelle and Chabrier 2008; Chabrier and Hennebelle 2010). This concept of turbulent Jeans mass for collapse has received some support from numerical simulations aimed at exploring this issue (Schmidt et al. 2010). Later on, also using analytical tools originally developed for cosmology, Hopkins (2012) generalized the concept of Hennebelle and Chabrier to larger, galactic scales, which yields the mass function of giant molecular clouds in galactic disks. As in the Hennebelle-Chabrier theory, the stellar IMF in the Hopkins formalism is entirely determined by one single parameter, namely, the turbulent velocity power spectrum index.

Future Directions

The striking resemblance between the prestellar core mass function and the final stellar IMF, added to the growing evidence for this latter being the combination of a Salpeter power law at large masses and a lognormal form below about one solar mass, clearly points to two fundamental results for the origin of the IMF. First of all, this latter seems to be imprinted in the cloud at the very early stages of star formation and be determined by the very conditions in the cloud, density, temperature, and large-scale Mach number. Second, observations and numerical simulations show that compressible turbulence, with or without the presence of a magnetic field, leads to a roughly lognormal distribution of overdensities mirroring the shape of the IMF. As discussed above, this concept of turbulence-induced fragmentation for the origin of the IMF can now rely on a sound theoretical support, which shows that the very shape of the IMF is entirely determined by the density and velocity power spectra of compressible turbulence, which are universal properties. Quantitatively speaking, however, the IMF, notably its extension in the low-mass domain, depends on the essential properties of the cloud, density, temperature, and large-scale Mach number. Under standard Milky

Way-like molecular cloud conditions, these properties obey Larson's relations and display rather similar values, leading to a rather universal IMF. It is not excluded and is indeed predicted by the above theories, however, that under quite different conditions, for instance, in extreme environments, the IMF might differ *quantitatively* from the one inferred in the galactic neighborhood, in particular for the peak position and the extension in the low-mass regime. If the theory is correct, however, the IMF should qualitatively remain the same, with a high-mass power law tail rolling down to a lognormal form below about the characteristic thermal Jeans mass of the medium.

Future observations, both in the galactic neighborhood and in extragalactic or widely different environments, should allow us to test further these theories and verify the robustness of this general paradigm for the origin of the stellar initial mass function.

Alteration · Extraterrestrial · Insoluble · Organic matter · Unusual isotopic composition

Synonyms

IOM; Kerogen-like matter

Definition

Insoluble organic matter (IOM) is a major component of organic matter found in primitive extraterrestrial materials such as carbonaceous meteorites. Most of this is organic carbon with lesser amounts of hydrogen, nitrogen, oxygen, and sulfur forming aromatic hydrocarbon cores (two to four aromatic rings) and short-chain aliphatic hydrocarbons with various functional groups including nitrile, carboxyl, and ether. Unusual isotopic signatures such as extreme δ and ^{15}N -enrichment are observed.

Overview

Insoluble organic matter (IOM) is a major constituent of organic matter in extraterrestrial materials. Even though various organic compounds including amino acids, carboxylic acids, and polycyclic aromatic hydrocarbons (PAHs) have been identified in meteorites, particularly in carbonaceous chondrites, these solvent-extractable organic compounds are only 10–30% of the total organic carbon. Most meteoritic organic matter is insoluble in water, acids, or organic solvents. This insoluble organic matter is used to be called kerogen-like material (cf. kerogen is a solvent-insoluble organic matter in terrestrial rocks) or macromolecular organic matter. Now, it is generally called IOM.

For the ► [Murchison meteorite](#), which is relatively enriched in soluble organic compounds, the IOM consists of more than 90% of the meteoritic organic carbon with minor amounts of hydrogen, nitrogen, oxygen, and sulfur. Although the chemical structure of IOM has not been defined accurately yet, it has aromatic hydrocarbon cores (two to four aromatic rings) with short-chain aliphatic hydrocarbons. IOM from various meteorites has a wide variation in

chemical composition. The H/C ratio of chondritic IOM varies from <0.1 to 0.7 , the more metamorphosed meteorite having a lower H/C ratio. Therefore, the H/C ratio is a sensitive indicator for thermal processing during the meteorites' history. ^{13}C -NMR and ► [XANES](#) studies have also revealed various chemical bonding and functional groups, including aromatic and aliphatic structures with carbonyl, carboxyl, and aldehyde as well as amide and nitrile groups. As the Murchison IOM generates abundant PAHs and acetic acid (ca. four times higher compared to solvent-extractable acetic acid) during hydrous pyrolysis, the IOM may be an important precursor for organic compounds in meteorites.

The most primitive IOM also possesses unusual isotopic signatures such as extreme δ and ^{15}N -enrichment, which have not been observed in solar system processes. Such isotopic behavior suggests that meteoritic organic matter may have originated from interstellar processes. However, the unusual isotope signals are diminished or lost during the thermal and aqueous alteration on meteorite parent bodies.

Definition

Intelligence is a term referring to a range of abilities that have to do with how an individual (or collective entity) acquires, processes, stores, analyzes, and acts upon information and situations. It includes capacities such as memory, learning, problem solving, abstract thinking, creativity, and behavioral flexibility. Intelligence is, by nature, a fuzzy concept. That is, there are no strict boundaries on it and there is no scientific consensus on its definition. Intelligence is often referred to as cognitive complexity.

Overview

In the domain of ► [SETI](#), intelligence has been operationalized as the presence of a technology detectable from Earth. In the broader framework of astrobiology, however, there is no need to limit the study of intelligence to a strict technical criterion. The study of intelligence in the astrobiological paradigm involves applying our knowledge and understanding of the myriad intelligences on earth to develop scientific hypotheses about extraterrestrial intelligence. Intelligence is a reflection of the kinds of cognitive adaptations each species has had to make in its evolutionary history and is, thus, multidimensional, interacting

with many other adaptive features, such as sensory-perceptual and motor abilities.

Intelligence across species on this planet is measured in a variety of ways. These include experimental studies of learning, memory, and other aspects of cognition in animals. It also involves determining what cognitive capabilities are evinced in animals in a natural setting. There are trade-offs with the validity of both approaches. Several neuroanatomical measures are used as proxies for intelligence across species, including relative brain size (also known as encephalization quotient), the volume of specific structures in the brain, and nerve cell density and connectivity. Some combination of all of the above features within the categories of brain size and organization forms the neurological basis of the phenomenon we know as intelligence. Correlations among various measures of brain size, cognitive capacity, problem solving, and behavioral ecology, e.g., social complexity, dietary complexity, have been found in many groups of animals across phyla. These patterns of association point to possible scenarios about the causal relations between intelligence and the physical and social environment. The challenge is to determine how all of these features relate to each other to form the range of intelligence that exists both within and across species on earth.

Basic cognitive processes forming the fundamental groundwork for intelligence in animals are found in unicellular organisms as mechanisms of learning and memory are shared across all species, including humans. There are fundamental capacities which even simple nervous systems allow which are ubiquitous among all motile life forms on earth. And there is a deep continuity in the domain of intelligence across species. Likewise, in metazoans, intelligence is often correlated with other psychological capacities such as self-awareness, emotional complexity, and personality structure. Even “high-level” cognitive abilities once thought to be exclusively possessed by humans, such as for planning, basic mathematics, self-recognition, and a technological culture, are not unique to our species.

Definition

Intelligence, those features of an organism that mediate the way in which that organism represents, processes, and acts upon information, is a biological trait subject to the same evolutionary principles that shape all other biological features of organisms on this planet. The evolution of intelligence refers to the pattern, distribution, and mechanisms of neurobiological, cognitive, and behavioral characteristics within and across species over time. The question of the evolution of intelligence is often framed as one of cognitive (psychological) complexity.

Basic Methodology

The main task in studying the evolution of intelligence is to find ways to reconstruct the past and place the cognitive characteristics of modern species in the proper temporal and phylogenetic context. This begins with a well-supported phylogenetic tree, i.e., a branching diagram of species showing their inferred evolutionary relationships based on physical and genetic traits. Connected taxa on the tree are implied to have descended from a common ancestor. Nodes represent species or some other taxonomic unit and branch lengths, often, are used to represent time. Phylogenetic comparative methods are then employed, using the tree, to test for patterns of evolutionary change from which we can draw inferences about the evolutionary process.

The kinds of data used to develop a phylogenetic tree range from phenotypic, behavioral, and anatomical traits to genotypic characteristics. Comparative phylogenetic analysis provides a way to, for instance, infer the ancestral state of a given trait, e.g., toolmaking or mirror self-recognition, or whether there is evidence for convergent evolution in some component of intelligence. The actual data compared against a phylogenetic framework derive from a variety of approaches.

Research on intelligence in living animals is typically conducted using two approaches: laboratory-based experimental studies and

observations in a naturalistic ethological setting. There are trade-offs with the validity of both approaches, and this is why both must be combined to understand intelligence in a comparative evolutionary framework. The strength of laboratory-based experimental tests of cognition is that they can be well controlled for extraneous variables, providing a way to test specific hypotheses about the existence of certain capacities in a species. The weakness in this approach is in the questionable generalizability to a natural setting. The challenge for laboratory-based approaches when studying animal intelligence is to devise tasks which are species appropriate, i.e., tap into the natural proclivities and sensitivities of the species. Yet, despite the artificial setting of a laboratory, many members of other species score high marks on human-devised tests of intelligence and even exceed human performance in specific domains. For instance, chimpanzees far exceed human performance on numerical short-term memory tests under equivalent laboratory conditions, i.e., using a touch-sensitive computer screen (Inoue and Matsuzawa 2007).

The other approach, known as cognitive ethology, assesses abilities of animals in their natural habitat and therefore frames intelligence more directly as a set of cognitive adaptations to a specific ecological niche over evolutionary time. Studies in this domain do not always feature the tight controls of a laboratory study but can provide a more appropriate setting for the display of abilities that might be restricted and thus unobserved, under artificial conditions. For instance, our knowledge of cultural transmission in chimpanzees, orcas, sperm whales, and many other species could only come from field studies over long periods of observation. The cognitive ethological approach provides a window into the adaptive significance of behaviors and abilities in other species, providing insights into how and why the many facets of intelligence evolved across species on this planet.

Another method used to obtain data about the evolution of traits related to intelligence is through the fossil record. This approach, called paleoneurology, is the study of brain evolution by analysis of fossil skulls and endocasts.

A brain endocast is the imprintation of the inner features of a cranium that captures the details created from pressure exerted on the skull by the brain itself. Endocasts can be formed naturally by sedimentation which enters the skull through the cranial foramina and hardens over time or artificially by creating a mold from silicon or latex that reproduces the inner structure of the cranium. While complete natural endocasts are rare and artificial ones dependent upon a clean interior cranial space, the state-of-the-art method for seeing inside the cranium is computed tomography (CT), which can be used if the skull is filled with or encased in hardened matrix. CT is employed to reconstruct the shape of the brain *in vivo*, estimate cranial volume (or brain size), and conduct other morphometric analyses. These data are then used to infer evolutionary changes in the brain thought to reflect changes in cognitive abilities. These data are analyzed against existing trees and also provide more data for improved trees. Moreover, and importantly, these endocranial characteristics are compared with those of modern species to infer evolutionary routes of traits associated with intelligence. Of course fossil data is only obtainable from specimens that are preserved in the record as actual fossils or, in some cases, trace fossils. Trace fossils can be used to infer behavior. However, the limitation on the paleontological method is clearly the relative paucity of preserved data from very early in the Earth's history. CT is most applicable to the study of vertebrate brain evolution for these reasons.

Another particularly productive approach to research on the evolution of intelligence and the brain involves combining the knowledge bases and methodologies of developmental biology with evolutionary biology, an approach called ► [evo-devo](#). The evo-devo approach is to examine the way mechanisms of development have been influenced by, and reveal, evolutionary forces and vice versa. Developmental patterns are shaped by phylogenetic relationships, and evolution is influenced by genetic modifications during early development. This approach has revealed much about the genetic mechanisms behind such characteristics as brain segmentation and brain-to-body scaling.

Finally, it is important to note that none of the above approaches to studying the evolution of intelligence are entirely mutually exclusive. Data from studies of cognitive abilities in living animals, fossil evidence of changes in brain size and shape, and genetic mechanisms underlying the development of the brain and the rest of the nervous system are brought together to create an ever-growing picture of the evolution of intelligence at the multiple levels required to understand such a complex aspect of organisms.

Key Research Findings

The evolution of intelligence on Earth is characterized by evolutionarily highly conserved processes and, thus, a great deal of continuity across phyla. The actual nature of the first organisms and the exact circumstances of the origin of intelligence will be forever unknown. But research on extant organisms using techniques to reconstruct phylogenetic relationships can aid in identifying the major milestones in the evolution of intelligence from brain-like functions in unicellular organisms to the development and centralization of the nervous system in metazoans. These evolutionary processes reveal a shared set of fundamental cognitive characteristics across all species and lead to the deep insight that all brains and intelligence on Earth, including those of humans, are a variation on a universal theme laid down 600 million years ago with the appearance of the first animals.

Intelligence in Early Unicellular Life

The need to process and act upon information is intimately tied to the varied distribution of elements in the environment that impact survival. An immobile organism or one living in a highly predictable, stable environment would not have much need for a nervous system. But motile organisms must have a way to detect and analyze the range of information in their environment and make adaptive behavioral responses to it. Motile bacteria, for example, are attracted or repelled by various stimuli and need to be able to act upon detection of these inputs. They exhibit taxes,

guided movements to a stimulus, which include ► **chemotaxis**, phototaxis, energy taxis, and magnetotaxis. Therefore, the first stage in the evolution of intelligence arose very early in the Earth's history with the emergence of motile single-celled organisms. They sense their environment, briefly store the information, integrate it in different channels of input, and then act upon it – producing basic adaptive behavior. These brain-like processes work at a molecular level but they reveal a common ancestry with all modern brains.

The mechanism by which unicellular organisms detect their environment is known as “membrane excitability” and involves sensitivity to electrochemical gradients typically accomplished through the flow of ions into and out of the cell. This basic mechanism was built upon and adapted to become the basis of information flow in neurons, cells specialized for information processing, in metazoans. Evidence for continuity derives from the fact that the membranes of modern neurons operate by the same electrochemical principles (voltage-gated ion movement across a membrane) as in single-celled organisms (Allman 1999).

One example of a bacterium with brain-like capacities is *Escherichia coli*, which senses its environment through a dozen different types of protein receptors embedded in its cell wall that allow chemicals outside the cell to communicate with mechanisms inside. Each receptor specializes in a specific kind of information or input, e.g., toxins, sugars, amino acids, etc. The input is integrated, and the result is the “decision” to behave in a certain way, i.e., use of its flagellar motors to swim toward or away from the environmental stimulus. Another unicellular organism, *Halobacterium salinarum*, derives energy from light in the orange spectrum. It possesses a light-sensitive pigment similar to rhodopsin, the photo-receptive pigment in vertebrate eyes. Detection of orange light causes the *Halobacterium* to swim toward the source (Allman 1999). These simple responses were elaborated upon to allow for more complex behavior in metazoans.

The fact that all mobile unicellular organisms possess the fundamental characteristics of

nervous systems suggests that the two critical factors for the early emergence of intelligence on any planet are environmental variability and motility. With environmental variation, a way to sense and act upon that environment to optimize one's survival will inevitably evolve. Thus, environmental variation is key to the emergence of nervous system functions and the potential for complex intelligence.

The Evolution of Intelligence in Metazoans

When metazoans (multicellular animals) appeared, approximately 600 million years ago, cells became specialized for different functions. The next major milestone in the evolution of intelligence was the specialization of some cells with excitable membranes as neurons. The neuron is the basic unit of information processing in all nervous systems on Earth and has remained, fundamentally, unchanged since early metazoan evolution, with only some smaller modifications added later, e.g., myelination of fibers to increase transmission fidelity and efficiency. A neuron is an electrochemically polarized cell which controls the flow of information through the organism. It has a characteristic architecture consisting of a body with branching processes, called dendrites, containing chemical receptors. When the dendritic input reaches an electrochemical summation threshold, a long axon transmits an electrical pulse to terminal branches which then release chemicals (neurotransmitters) that are picked up by the dendrites of another neuron and so forth. Importantly, information flows from the dendrites to the cell body and is converted into all-or-none signals, action potentials, which are relayed along the axon to the terminal branches. (These characteristics of directionality and “digitization” of neural impulses set the stage for an unprecedented level of organization and neural computational potential in the bilaterians).

The early radially symmetrical metazoans, e.g., cnidarians, ctenophores, hydrozoa, etc., were the first animals to possess a nervous system of any kind. Theirs is a decentralized nerve net (a loose arrangement of sensory neurons connected to motor neurons by interneurons).

While these animals lack a level of organization found in the nervous systems of bilaterians, the shared basic characteristics of these early nervous systems and more modern brains are striking. Voltage-gated sodium channels are present in jellyfish neurons and all modern brains. The neurotransmitters coursing through the brains of all modern species, including those with nerve nets, were derived from simple amino acids with precursors in single-celled organisms. In many of these radially symmetrical animals, there are the very beginnings of the next step in the evolution of nervous systems, centralization, in the form of nerve rings and clusters of neurons called ganglia which allow these animals to exhibit complex behaviors requiring coordination of parts of the body. Despite possessing no brain, many animals with nerve nets evince simple learning capacities, such as habituation, and can navigate complex environments.

Intelligence in Bilaterally Symmetrical Invertebrates and Vertebrates

The third major milestone in the evolution of intelligence coincided with the appearance of bilaterians (laterally symmetrical animals) 550–600 million years ago. Early bilaterians were wormlike creatures with a nerve cord running down the body and an enlarged ganglion at the front or head region. The process of enlarging the ganglionic cluster at the head region along with the sensory organs is called encephalization, and this process led to the first central nervous systems or brains. An anterior bilobed (left- and right-sided) brain connected to a nerve cord became the bauplan of the nervous system for all organisms with a central nervous system. The earliest true brains were segmented and differentiated into regions and structures. The first vertebrates, who appeared about 500 million years ago, evinced the characteristic four-part segmentation plan which all modern vertebrate brains adhere to: a telencephalon (part of the forebrain, including the neocortex), diencephalon (also forebrain), mesencephalon (midbrain), and rhombencephalon (hindbrain). And all vertebrates possess the same brain structures within those segments. In addition to the

basic layout, the function of structures within these segments is highly conserved across all vertebrates.

From an evo-devo perspective, the connection between vertebrate and invertebrate brains is evinced in the embryonic development of nervous systems across species from different phyla (Striedter 2005). The genetic mechanisms underlying nervous system formation also reveal a strong degree of conservation. For instance, homeotic genes that segment insect bodies are co-opted to segment parts of the vertebrate central nervous system. Other genes controlling the formation of part of the brain in fruit flies are replicated and regulate the newest part of the mammal brain, the neocortex. Therefore, even the human brain is organized by genes with antecedents going back half a billion years (Allman 1999).

Neurobiologist Eric Kandel and his colleagues have shown that the basic neural mechanisms of learning are the same from mollusks to mammals (Kandel 2009). But the range of shared cognitive capacities is not limited to very basic processes. Members of the phylum Mollusca (octopus, squid, cuttlefish, and nautilus) exhibit complex cognitive and behavioral abilities on a par with vertebrates, including social learning and tool use. Insects and arthropods, too, exhibit a vertebrate level of intelligence in many domains. For instance, in addition to their complex collective or swarm intelligence, individual bees understand counting, abstract concepts, and categorizations. These findings of cognitive complexity in invertebrates reveal a striking insight about the evolution of intelligence on Earth. The basic capacities of the human mind are demonstrable in the minds of beings who we commonly viewed as very different from us. These capacities in invertebrates – learning concepts, counting, and even tool use – point to the continuity of mind among humans and all other animals at a deep evolutionary level.

Within the realm of vertebrate intelligence, which arose about 500 million years ago, there is a striking degree of shared cognitive complexity across many species. Differences in even the most complex “high-level” capacities can be best

understood as varying along a continuum of complexity, as there are no cognitive abilities that are completely unique to any species, including humans. Even the most sophisticated components of intelligence, i.e., symbolic thinking and communication, self-awareness, and culture, are distributed across vertebrate species because all intelligences on Earth derived from preexisting capacities and the need to solve similar problems for survival. The centralized nervous system found in all animals and, in particular, the vertebrate brain and spinal cord are variations on the same basic theme.

Interest in the evolution of intelligence has been framed as a “rewinding of the tape of life” to address hypotheses about the causes and drivers of changes in brain and intelligence. Historically, studies of brain allometry (how brain size scales with body size) have focused on variations in adult brains and how they might be related to brain size and morphometry, sensory and motor specializations, and behavioral and ecological niches. Though evolutionary hypotheses cannot ever be tested directly by going back in time, correlational analyses can provide some insight into the drivers of evolutionary patterns. The conventional approach is to interpret correlations as proxies for “as-yet-unknown” causal relationships. Such studies in recent years have benefited from enhanced technological methods of measuring brain size (e.g., computed tomography), the collection of large behavioral databases, and application of powerful statistical tests to such data. Collectively, this body of scientific work has brought to light some broad consistent patterns of association among brain size, cognition, and ecology across animal groups that can be summarized as follows: Various measures of brain size (e.g., encephalization quotient, brain–neocortex ratio, etc.) are positively correlated with (1) feeding innovation rate, learning, and tool use in birds and primates; (2) behavioral repertoire size in mammals; (3) social complexity in birds, primates, carnivores, and some insectivores; and (4) dietary complexity in primates. These associations between neural mass and complexity, individual cognitive ability, and social complexity point to

the possibility that there may be general or even universal principles that shape intelligence on this planet – and perhaps, by extension, on others.

Brain Size and Organization

Brains are modified in various ways to reflect the adaptive specializations of each species. Encephalization, the process of elaborating on the size of the brain, is one dimension by which species differ. One measure of brain size or encephalization is the encephalization quotient (EQ). EQ is a statistical measure of average brain size relative to average body size for a species taking into account the fact that brain and body size are not independent. EQ is calculated by regressing average brain size onto body size for a wide range of species. Therefore, EQ is a normalized metric allowing one to compare directly the encephalization level of a cat and an elephant. A species with an average brain size expected for its body size has an EQ of 1 and lies on the regression line throughout the full range of body sizes. Modern humans have an EQ of 7.0, i.e., our brains are seven times larger than one would expect for an animal of our body size. Many cetaceans (dolphins and whales) possess EQs in the 4.0–5.0 range, and our nearest relatives, the great apes, have brains 2.5–3.0 times larger than expected. Species with EQ values of less than one have smaller brains than expected on the basis of body size. Encephalization should always be interpreted within the context of phylogeny. For instance, despite the fact that crow brains are smaller in absolute size than many mammal brains, the crow brain is much larger as an avian brain than, say, a camel brain, which is as a mammal brain. And crows, with EQs >2.0, are considered among the most intelligent of birds, whereas camels, with EQs closer to 1.0, are quite average as mammals on a cognitive level.

There are a number of scaling factors which come into play when brain size is modified that impact brain organization. These include preservation of neural conduction time and connectivity, which are addressed by increasing axon (fiber) diameter through myelination

(adding an insulating covering to the axon) and increased multiplication of local connectivity through modularization. The result is that, across species, larger brains containing more white matter (myelinated fibers) than gray matter (cell bodies) are less dense (due to increases in glial cells to support the larger neurons) and more modularized (maximizing local conductivity). These changes are observed in all brains and represent a universal set of principles for how brains change in size and organization over evolutionary time.

Evo-devo studies have revealed mechanisms underlying the conservative nature of the way in which bodies, including brains, have developed and evolved across taxa. The same genes are used repeatedly to create species-specific differences in body plan, including the brain and the rest of the nervous system. Current evidence shows that there is a very limited set of potential ways genes can alter development to create variety in nervous systems across species. And this point becomes the basis for the fact that all brains are a variation on the same theme. Diversity in the number of brain segments, basic segmental structure, and neural circuit organization are rare as are changes in the molecules which make up neurotransmitters and neuromodulators. On the other hand, changes in relative brain size or the volume of specific brain structures (allometric changes), in the morphology of single neuron types, and in the distribution of neurotransmitter substances occur commonly. The evolution of intelligence is, therefore, a history of modifications in some aspects of brain development more than others. The predominant way genes shape brains is through the timing and duration of sequences of neurogenesis and cell cycle rates. This results in correlations between brain size (and related measures) and life-history parameters, such as gestation length and length of the juvenile period. These life-history parameters, in turn, are related to aspects of intelligence, for instance, how much of an individual's life is spent learning before adulthood. Therefore, there are basic patterns of commonality across species with regard to neurogenetic, developmental, and evolutionary components of intelligence.

Common Biases

Darwin laid the groundwork for our modern understanding of evolution as a dynamic process shaped, mainly but not entirely, by the mechanism of natural selection, and his work is the basis of current methods of comparative phylogenetic analyses. Life on Earth, and thus intelligence, is characterized by a nonlinear branching pattern of taxonomic relationships over time (the phylogenetic tree). No modern species are ancestral to any other modern species. Likewise, no modern species is more advanced than another modern species. However, our current understanding of intelligence is fraught with preconceptions which continue to bias thinking to this day.

The most pervasive and insipient model of life on Earth and, thus, the distribution and nature of intelligence on Earth is known as the *scala naturae* or great chain of being. According to this model, nature is arranged on a linear scale of progression with inorganic substances and objects, e.g., rocks, on the lowest rung, then plants, then up to "lower" animals (invertebrates), then vertebrates, then to "higher" mammals such as primates, and, finally, humans, who occupy a separate, superior position above all other animals. Even Darwin's phylogenetic tree is often referred to as the phyletic scale, preserving the linear concepts of the *scala naturae*. Although few adhere to the *scala naturae* model explicitly, it still implicitly dominates our way of thinking about our own species and the rest of nature.

The incorrect assertion that humans are (1) qualitatively different from and (2) superior to other animals has led to a number of biases and false assumptions about the evolution of intelligence on Earth, e.g., anthropocentrism, typically embodied by the anthropic principle, which imbues much of the thinking about extraterrestrial intelligence. The historical result has been an unending and misdirected argument about contingency versus convergence between those who view intelligence in the narrowest sense, that is, as human intelligence, and those who take a broader view.

Scala naturae thinking is also closely related to teleological assumptions about intelligence. Teleology is the appeal to a goal-directed, purposeful

progression toward an end point as a means of explaining phenomena. Teleological thinking suggests that all life on Earth has been a progressive move toward the eventual emergence of human intelligence. It is entirely understandable that one would propose this after examining average relative brain size (a biological proxy for intelligence) across species over the last 200 million years. The result is a graph with a positive slope which seems to make the case for a progressive increase in brain size and intelligence over time. But this is an illusion in the fossil record. When understood properly, this graph represents the fact that brains simply need time to get large and, thus, larger brains are found in more recent species. When proper phylogenetic analyses are conducted, there is no directional trend. There is no evidence for any progressive linear trends in biological evolution which lead to humans. There is no “lower,” no “higher,” no “advanced,” and no “primitive” among extant species. To summarize, teleological and anthropocentric notions about the evolution of intelligence are not supported by any scientific evidence and should be avoided.

Future Directions

Moving forward, studies of intelligence and how it evolves should become increasingly ecologically valid as we begin to fold in several lines of data to seek insights into how and why intelligence evolves. Computational abilities currently provide a way to take a big data approach to analyzing behavior, ecology, genetics, etc. and looking for patterns of correlation which may support certain hypotheses about the evolution of intelligence on Earth. So much of the data relevant to the question of the evolution of intelligence has not yet been mined, brought together, and analyzed in the framework of extraterrestrial intelligence, so there is tremendous potential to be realized. Finally, progress can only be made if we shed preexisting assumptions and biases about intelligence which are inconsistent with the scientific evidence and adopt, instead, a more inclusive non-anthropocentric approach to the study of the evolution of intelligence on Earth.

Definition

Astronomical interferometry is an observing technique that makes use of several separate sub-apertures instead of a single, large-aperture light collector for the observation of celestial objects. The separation between two individual sub-apertures is called the baseline and defines, together with the observing wavelength, the resolving power of the instrument. The longer the baseline and the shorter the wavelength, the higher the resolving power. Astronomical

interferometry is currently operational in the radio, infrared, and visible ► [wavelength](#) ranges. The presently available facilities give access to angular resolutions of the order of 1–10 millisecond of arc (milliarcsecond, abbreviated as *mas*), i.e., ten to hundred times smaller than that provided by the ► [Hubble Space Telescope](#) or 8–10 m class ground-based telescopes equipped with adaptive optics.

History

Interferometry's application to astronomy was first implemented in the visible in the late nineteenth and early twentieth centuries (Lawson 1997). The first measurement of the angular size of a star (Betelgeuse) was obtained in 1921 by Albert A. Michelson and Francis Pease using interferometry in the visible. Its development as a mainstream observing technique effectively started in the 1950s in the radio domain, at wavelengths for which the constraints on the quality of the reflector surfaces and optical path length equalization are less stringent than in the optical. Several giant radio interferometers were built in the 1970s and 1980s. In the 1960s, intensity interferometry in the visible was developed by Robert Hanbury Brown and Richard Q. Twiss in Australia. It was soon followed in the 1970s by the first multi-telescope observations in the visible, obtained by Labeyrie (*Interféromètre à 2 Télescopes*, I2T, followed by the *Grand Interféromètre à 2 Télescopes*, GI2T).

Several optical interferometers with collecting telescopes of a few decimeters to a meter were built in the 1980s and 1990s, including the Mark III (visible), the Palomar Testbed Interferometer (PTI, near infrared), the Navy Prototype Optical Interferometer (NPOI, visible), the Infrared Optical Telescope Array (IOTA, near infrared), the Infrared Spatial Interferometer (ISI, mid-infrared), and the CHARA array (visible and near infrared). As a remark, optical interferometry is not formally restricted to the visible domain, but includes the application of interferometric techniques from the blue to the mid-infrared wavelengths, for which the light is manipulated using optical mirrors or lenses.

Overview

Due to the diffraction laws of optics, the larger the telescope and the shorter the observing wavelength, the better the angular resolution (i.e., the smallest details on the sky that the telescope can distinguish). However, the cost of building a telescope increases rapidly with its size. Astronomical interferometry offers a relatively cost-effective way to achieve high angular resolution by using a cluster of comparatively small telescopes rather than a single, very expensive monolithic telescope. The light-collecting surface of a multi-aperture interferometer is naturally much smaller than that of a single aperture with the same diameter, thus limiting its sensitivity. In the optical-infrared domain, the Very Large Telescope Interferometer (VLTI) has recently achieved the first direct interferometric detections and resolved spectroscopy of giant [extrasolar planets](#). Future instruments installed in space have the potential to collect direct images and spectra of Earth-like

planets, as the absence of atmospheric turbulence permits very-high-contrast interferometric nulling observations (See “[► Nulling Interferometry](#)”).

The largest single-site radio interferometer is the Very Large Array (VLA, see Fig. 1), near Socorro, New Mexico, USA. Intercontinental interferometric observations were obtained with antennas spread over baselines of thousands of kilometers (Very Long Baseline Interferometry). Such extremely long-baseline observations are made possible in the radio domain by the fact that the amplitude of the electric field of the light can be recorded and recombined a posteriori, provided that accurate time signals are recorded with the data. This technique is generally not applicable in the optical. The international Atacama Large Millimeter Array (ALMA, see Fig. 2) is the largest radio interferometer at millimeter wavelengths, as well as one of the largest ground-based astronomical observatories ever built. Its 66 antennas, 7–12 m in diameter, can be positioned on baselines of 150 m–16 km,

Interferometry,

Fig. 3 The two 10-m Keck telescopes (Mauna Kea, Hawaii) were used together as an interferometer with a nulling capability for the observation of exozodiacal disks and exoplanets until 2012

allowing radio imaging observations down to an angular resolution of a few milliarcseconds.

In 2001, two large optical interferometers with collecting apertures of 8–10 m were inaugurated: the Keck Interferometer (KI, two 10-m telescopes, see Fig. 3) and the Very Large Telescope Interferometer (VLTI, four 8-m telescopes, see Fig. 4). These arrays include a variety of focal instruments that combine the light collected by the sub-pupils at different wavelengths in the near- and mid-infrared domains. The Keck Interferometer ceased operations in early 2012. The VLTI continues its development with a second generation of beam

combiners, GRAVITY and MATISSE that saw first light in 2015 and 2018, respectively.

Basic Methodology

The principles behind interferometry are founded on the wave properties of light. The superposition of light waves collected by the different sub-apertures results in an interference pattern whose properties are related to the structure of the observed object through the Zernike-Van Cittert theorem. The light waves that have the

Interferometry, Fig. 4 The Very Large Telescope Interferometer (Cerro Paranal, Chile) combines the light from four 8-m telescopes (in the background), or four 1.8-m telescopes (white spherical domes in the forefront)

same phase produce constructive interferences, while the waves that are out of phase produce destructive interferences. The accurate measurement of the interference pattern (i.e., the visibility and phase of the fringes) then gives access to the spatial structure of the observed object at very high angular resolution. In the optical, the sub-apertures are telescope mirrors, and the light is transported to the recombination point using a series of mirrors or optical fibers. One particular difficulty of interferometry is that the optical path length between the observed source and the recombination point must be equal for the light beams going through the different sub-apertures. The acceptable uncertainty on the path length is of the order of the wavelength. This constraint is particularly stringent for interferometers with long baselines operating in the visible, as path lengths of up to several hundred meters must be controlled with an accuracy of less than a micron.

Interferometric measurements can also be produced with a monolithic telescope by using the aperture masking technique. The principle of this technique is to insert a mask in the light beam collected by the telescope, punched with a number of holes arranged in a nonredundant pattern. This pattern is defined so that each baseline (the vector separation between two sub-apertures) is uniquely

defined on the mask. The focal image of the masked telescope is the same as that of a multi-aperture interferometer (i.e., is made of the superposition of fringe patterns). Compared to full-aperture imaging, aperture masking allows a more efficient recovery of the highest spatial frequencies (the finest details) observable by the telescope. This is achieved at the cost of a loss in sensitivity, since part of the telescope aperture is covered by the mask, and an increased complexity of the data analysis. The extremely large telescopes currently under development all employ segmented primary mirrors and are therefore similar in principle to multi-aperture Fizeau interferometers.

A variant of classical interferometry is called intensity interferometry. This technique uses two light detectors, typically either radio antennas or optical telescopes. Both detectors are pointed at the same astronomical source, and intensity measurements acquired at very high frequency are transmitted to a central correlator facility. The intensity interferometer measures interferometric visibilities like all other astronomical interferometers. These measurements can be used to measure, for instance, the angular diameter and limb darkening of stars. However, with intensity interferometers, aperture synthesis images are more

difficult to produce as the phase information of the fringes is not preserved. Novel approaches have been proposed to circumvent this difficulty and obtain interferometric images at visible wavelengths from intensity interferometry (e.g., Gori et al. 2021).

Key Research Findings

Radio interferometry was used successfully to image the vicinity of black holes and quasars, the surfaces of nearby stars, and to obtain high-precision astrometric measurements. Most remarkably, the combination of a number of millimeter wavelength telescopes (including ALMA) in the Event Horizon Telescope provided in 2019 an interferometric image of the accretion disk of the black hole at the core of the M87 galaxy. The analysis of the polarization properties of the collected light enabled the measurement of magnetic field in the disk (Fig. 5).

The position of quasars measured by radio interferometry is the basis of the definition of the International Celestial Reference Frame.

Interferometry, Fig. 5 Image of the disk surrounding the supermassive black hole of the M87 galaxy, obtained by the Event Horizon Telescope in 2019. The orientation of polarization is represented with the curved lines, tracing the magnetic field in the disk. (Credit: EHT Collaboration)

Historically, optical interferometry produced important results essentially in the stellar physics field. The first optical interferometric images of the surfaces and close environment of stars of various classes were obtained in the early 2010s, as well as high-resolution observations of a sample of active galactic nuclei in the near- and mid-infrared. The imaging capabilities of optical interferometers are progressing rapidly. However, they are traditionally used to constrain model parameters (e.g., stellar angular diameters, limb darkening coefficients, circumstellar environment of young and evolved stars, and binary orbits) rather than reconstruct *ab initio* interferometric images, due to their relatively small number of apertures compared to radio interferometers.

The dual field GRAVITY beam combiner at ESO's VLTI interferometer (GRAVITY Collaboration 2017) can measure differential astrometry of two targets located within 2–5 arcseconds (with the 8 m or 1.8 m telescopes, respectively) to an extreme accuracy of a few tens of microarcseconds. With this instrument, it is also possible to observe very faint targets close to brighter ones by integrating the fringe signal in one of the two channels of the interferometer, while using the other channel to compensate for the atmospheric turbulence using the bright object as reference. GRAVITY has been designed and successfully used to observe the immediate vicinity of the central supermassive black hole of our galaxy (Sgr A*) and measure the orbits of the neighboring stars. GRAVITY has also contributed to the exoplanet field by directly detecting, for the first time by interferometry, the giant exoplanet HR 8799e (GRAVITY Collaboration 2019) and the two giant exoplanets b and c orbiting in the Beta Pictoris system. These astrometric observations tightly constrain the orbital parameters and masses of the planets, and also provides their spectra with an unprecedented accuracy (Fig. 6). An upgrade of the GRAVITY instrument (the GRAVITY+ project) is expected between 2022 and 2024 to considerably improve the sensitivity and sky coverage of the instrument, enabling very high angular resolution observations of faint targets such as active galactic nuclei at high redshift or low mass exoplanets.

Interferometry, Fig. 6 The system of Beta Pictoris, whose planets b and c have been monitored using the VLTI/ GRAVITY interferometric instrument. (Credit: Axel Quetz/MPIA Graphics Department)

Future Directions

There exist several projects to install optical interferometers in space, where the environment is very stable and no atmospheric turbulence perturbation of the wave fronts is present. Apart from gravitational wave detectors (that use laser interferometry for metrology), the most advanced project for space interferometry is the Space Interferometry Mission (SIM) and its spin-off SIM-Lite, that were designed to obtain micro-arcsecond astrometric measurements in the narrow-angle regime. However, as of 2021, the development of interferometric astrometry in space is stopped. Such an extremely high accuracy permits the detection of the astrometric wobble induced on a star's position by the presence of orbiting planets, down to terrestrial masses. Other space projects include interferometric coronagraphs optimized for the observation of extrasolar planets, as well as ultraviolet and X-ray interferometers for stellar physics. The only operating interferometer presently in space is the Fine Guidance Sensor (FGS) of the Hubble Space Telescope. This three-aperture instrument is primarily employed to guide the telescope during scientific exposures, but has also produced important scientific results, such as the measurement of trigonometric parallaxes of nearby Cepheid variable stars.

New generations of interferometric instruments are specifically developed for high-contrast observation of the surroundings of nearby stars. The principle of these instruments is to recombine

the light from the target star in a destructive way: the in-phase light from the central star collected by one sub-aperture is cancelled by its superposition with 180° phase-delayed light from another sub-aperture. This technique, called nulling interferometry (the instrument being called a nuller) or alternatively dark fringe interferometry, can be understood as the interferometric version of the coronagraph. It is particularly promising for the observation of extrasolar planets and exozodiacal disks, as it provides simultaneously high-contrast and high-resolution observing capabilities (Defrère et al. 2022). An interferometric nuller was successfully operated on the Keck Interferometer (the KIN instrument) up to 2012, and projects exist for the development of an interferometric nuller in space.

Interior outgassing

Definition

Interior degassing is the process of ► **volatile** elements, such as carbon, hydrogen, and oxygen, being released from the solid planetary body

(i.e., the ► **crust** and ► **mantle**), into the atmosphere. This occurs through volcanism and volatile escape through the lithosphere as a result of intrusive magmatism and is influenced by large-scale, global processes such as mantle convection and ► **plate tectonics**. An important aspect of interior degassing is the chemical speciation of the volatile elements where, e.g., hydrogen can be outgassed as water (H₂O) or dihydrogen (H₂). Hence, it plays a major role in (the evolution of) the composition of the atmosphere.

Overview

During planetary accretion, volatile elements such as ► **carbon** (C), ► **hydrogen** (H), ► **oxygen** (O), ► **nitrogen** (N), and ► **sulfur** (S; together forming the C-H-O-N-S elements) are entrapped in the solid planetary body. During the lifetime of a planet these volatiles are released to form the atmosphere of the planet in a process known as “interior degassing or outgassing”. The most common outgassed species in the C-H-O-N-S system are ► **water** (H₂O), ► **carbon dioxide** (CO₂), dihydrogen (H₂), ► **carbon monoxide** (CO), ► **methane** (CH₄), sulfur dioxide (SO₂), ► **hydrogen sulfide** (H₂S), disulfur (S₂), ► **ammonia** (NH₃), and ► **nitrogen** (N₂). Besides that, minor amounts of chlorine, fluorine, and ► **dioxygen** compounds may occur.

In order to outgas volatiles from the solid interior of a planet, rocks first need to be sufficiently heated and/or depressurized such that they melt. Volatile elements are then initially dissolved in the melt. The amount of outgassing of the different gases does not solely depend on the abundance of the volatile elements they are composed of, but also the prevailing conditions of the ► **magma** and the atmosphere such as pressure, temperature, and ► **redox state** (i.e., the availability of oxygen to form chemical compounds). The solubility of volatiles is mainly dependent on pressure (Parfitt and Wilson 2008). Hence, when magma rises and the pressure decreases, volatiles that were initially dissolved in the melt form gas bubbles. Different species have different solubilities, with, e.g., 0.5 wt% water degassing more efficiently at lower

pressures up to 35 bar. In contrast, 0.5 wt% carbon dioxide is efficiently outgassed up to 220 bar (Parfitt and Wilson 2008).

Temperature and redox state of the magma influence the speciation of the gases with H₂O, CO₂, SO₂, and N₂ occurring in a more oxidized system, and H₂, CO, H₂S, S₂, and NH₃ outgassing from reduced magmas (Oppenheimer et al. 2011; Li and Keppler 2014). Methane outgasses at very low temperatures (<600 °C) (Ortenzi et al. 2020).

When a magma ocean is present in the early stages of planetary formation, the large amounts of near-surface melt result in the outgassing of the first (usually large) atmosphere of a planet (Nikolaou et al. 2019; Lichtenberg et al. 2021).

At later stages of a planet's evolution, like the conditions of present-day Earth, the melting of rocks is limited to smaller, isolated pockets within the planet's solid mantle, at shallow depths. Then, there are two main processes by which the gases in the melt can reach the atmosphere in order to outgas the interior. Firstly, gases are released to the atmosphere during volcanic eruptions in a process called “volcanic degassing.” As a second mechanism, intrusive magmatism, where the magma does not reach the surface of the planet, can also result in degassing. In this case, the gases in the melt travel to the surface through cracks and pores in the overlying porous rocks.

On Earth, the outgassing of the interior is balanced by the active recycling of volatiles into the mantle and crust through ► [subduction](#) processes in a geodynamic cycle. On other planets that feature predominantly stagnant-lid regimes like ► [Mercury](#) or ► [Mars](#), this recycling is largely absent, leading to the gradual depletion of the interior of volatile elements (Foley and Driscoll 2016; Noack et al. 2017; Tosi et al. 2017).

The concentrations of C-H-O-N-S elements in the atmosphere and the specific chemical species in which they occur affect the surface temperature and pressure of a planet. In addition, the elements of the C-H-O-N-S system are important building blocks for the molecules of life (Seager et al. 2016). As interior degassing plays a large role in providing these volatiles to the atmosphere, it is an important process that needs to be taken into account when assessing planetary habitability.

Definition

Extrasolar planets with relatively low masses (below $\sim 20\text{--}30 M_{\oplus}$) show a wide range of bulk

densities. This hints at a great compositional diversity, with planet classes that do not exist in the Solar System such as $\Rightarrow$ *Super-Earths* and $\Rightarrow$ *Mini-Neptunes* (Jontof-Hutter 2019; Spiegel et al. 2014). Models of the $\Rightarrow$ *interior structure* describe the hydrostatic and thermodynamic state of these planets. They provide radial distributions of density, pressure, temperature, and composition consistent with given mass and radius measurements. Due to the lack of observable planetary properties, interior structure models are often underconstrained and thus subject to large inherent degeneracies. Finding ways to break these degeneracies is a major goal in exoplanetary science.

Overview

In the $\Rightarrow$ *Solar System*, a wealth of information about the interiors of the planets is available from direct observations, space probes, and in situ measurements, which helps building a rather comprehensive picture of the internal structures of these bodies. Yet, all these observations are largely unavailable for exoplanets. Furthermore, so-called $\Rightarrow$ *Mini-Neptunes* and $\Rightarrow$ *Super-Earths* form two planetary classes with no equivalent in the Solar System. This poses a unique challenge in that many fundamental properties are difficult to constrain, and a definitive internal composition cannot be determined.

Owing to the wide diversity of observed exoplanets, a variety of computational models exists, from those designed to treat $\Rightarrow$ *gas giants*, where interior and atmosphere are closely interlinked, to those suited to describe $\Rightarrow$ *terrestrial planets* mainly consisting of iron and $\Rightarrow$ *silicate minerals* (rocks) (Perryman 2018).

Models aimed at characterizing the interior of low-mass exoplanets generally assume that the planet consists of layers with distinct physical and chemical properties (e.g., Sotin et al. 2007; Fortney et al. 2007; Valencia et al. 2007; Seager et al. 2007; Wagner et al. 2011; Zeng and Sasselov 2013). Metal and silicate rocks, ices, and gas are the three main compounds to form the bulk planet interior. In terrestrial (rocky) planets, the interior is dominated by rocky silicate $\Rightarrow$ *mantles* and

metal-rich $\rightarrow$ *cores*. Planets with large radii (above $\sim 1.6R_{\oplus}$, Rogers 2015) are instead likely to contain significant amounts of volatiles in the form of $\rightarrow$ *hydrogen-helium atmospheres* and heavier volatile species (“ices” such as H_2O and CH_4). The larger planets of this class are likely similar to Neptune and Uranus in terms of their interior structure ($\rightarrow$ *Mini-Neptunes*, see Nettelmann et al. 2011), whereas smaller planets could also be $\rightarrow$ *ocean planets* with rocky cores, but substantial amounts of water (Zeng et al. 2019).

More general models typically make no distinction between planet classes and treat the interior as composed of iron, rock, ice, and gas, permitting a wide range of possible internal structures to be addressed (e.g., Rogers and Seager 2010a; b; Dorn et al. 2017a).

The interior structure of a planet is governed by two main equations describing the mass distribution within a sphere and the condition of $\rightarrow$ *hydrostatic equilibrium*:

$$\frac{dm(r)}{dr} = 4\pi r^2 \rho(r)$$

$$\frac{dP(r)}{dr} = \frac{-Gm(r)\rho(r)}{r^2}$$

where m , P , and ρ are the mass, pressure, and density dependent on the radius r , and G is the gravitational constant. The link between density, pressure, temperature (T), and other state variables is given by a suitable $\rightarrow$ *equation of state* $\rho(r) = f(P(r), T(r))$.

Equations of state are commonly derived experimentally, and for more extreme conditions theoretical models and numerical ab initio calculations are employed (e.g., Baraffe et al. 2014a; b). For the treatment of the distribution of pressure and temperature within the atmosphere, dedicated models often substitute for the role of equations of state (e.g., Guillot 2010; Lopez and Fortney 2014).

It is often assumed that the temperature distribution within different interior layers follows an adiabatic gradient:

$$\frac{dT(r)}{dr} = \frac{\alpha(P, T)g(r)}{c_P(P, T)}T(r),$$

where α , g , and c_P are the thermal expansion coefficient, the gravitational acceleration, and the heat capacity, respectively. Processes such as radiogenic heating or viscous dissipation can lead to deviations from an adiabatic temperature profile (Bunge et al. 2001). While the temperature dependence typically only plays a secondary role in the silicate part of planetary interiors in terms of density, it plays a crucial role in the treatment of $\rightarrow$ *water-rich* and atmospheric layers (e.g., Thomas and Madhusudhan 2016).

$\rightarrow$ *Transit* and $\rightarrow$ *radial velocity* observations of exoplanets allow the determination of the planetary mass and radius. Mass-radius diagrams (Fig. 1) give a first indication of what a planet’s interior may look like by comparing it to theoretical curves describing spherical bodies of homogeneous composition (Swift et al. 2011). A planet larger than one made of pure rock must contain some amount of lighter species such as water, or have an extended atmosphere. However, with only mass and radius, it is not possible to infer a unique interior structure. Instead, due to the problem being underconstrained, there exists a wide range of degenerate solutions with different radial mass distributions that fit given mass and radius equally well (Fig. 2). This is only exacerbated by mass and radius measurement uncertainties. Moreover, without extensive follow-up studies, for most exoplanets mass and radius will remain the only available measurements.

A number of approaches have been developed to treat and quantify the degeneracy of exoplanetary interiors, such as Bayesian inference models using Markov Chain Monte Carlo sampling (Rogers and Seager 2010a, b; Dorn et al. 2017a), or machine learning models (Baumeister et al. 2020).

Efforts are being made to find observable parameters which can break these degeneracies. Spectroscopic measurements of exoplanetary atmospheres ($\rightarrow$ *Atmospheric Retrieval for Exoplanets*) can give indications toward the existence of an atmosphere and its composition (e.g., Miller-Ricci et al. 2008). The stellar abundance of refractory elements such as Mg, Fe, and Si may help to constrain the mineralogy of an

Interior Structure of Low-Mass Exoplanets,

Fig. 1 Mass-radius diagram of exoplanets below $30 M_{\oplus}$. The dashed lines show the theoretical mass-radius relation for planets with homogeneous composition (pure iron, silicate rock, or water ice). (Exoplanet data is taken from exoplanet.eu (November 2021))

Interior Structure of Low-Mass Exoplanets,
Fig. 2 Three examples of qualitatively different interior structures which all fit the well-studied exoplanet GJ 1214 b ($8.17 \pm 0.43 M_{\oplus}, 2.742^{+0.050}_{-0.053} R_{\oplus}$ Cloutier et al. 2021). The mass and radius of GJ 1214 b could be explained in

terms of a Super-Earth (solid line) with an iron-rocky core and an extensive gas envelope, or a volatile-rich $\rightarrow$ ocean planet (dashed line), or some mixture of the two (dotted line). (See also Rogers and Seager (2007) and Nettelmann et al. (2011))

observed planet (e.g., Dorn et al. 2017b; Brugger et al. 2017; Hinkel and Unterborn 2018).

Temperature

Definition

Models of the interior structure of a ► [planet](#) or ► [satellite](#) give the variations of thermodynamic state variables as functions of radius (starting at the center) or depth (starting at the surface). The thermodynamic state variables are pressure, temperature, density (or specific volume), and the concentration of chemical species. In many cases chemical layering is described in more specific terms as ► [crust](#), ► [mantle](#), and core or in shells described by characteristic elements, ► [minerals](#), and phases. In other circumstances shells are characterized by their rheological or transport properties such as the ► [lithosphere](#).

Overview

Knowledge of the interior structures of planets and satellites is a major prerequisite for understanding the evolution of planets and for models of how planets work. From a thermodynamic point of view, planets can be regarded as heat engines that convert thermal and gravitational

energy into mechanical work and ► [magnetic field](#) energy and evolve by differentiating, cooling, and contracting. The process of converting thermal or chemical energy into magnetic field energy is the ► [dynamo](#) process. The process that converts energy into mechanical work in ► [terrestrial planets](#) and satellites is associated with mantle convection and is discussed in the section on ► [heat transfer \(planetary\)](#). Mantle convection is the most important heat transfer mechanism in terrestrial planets and satellites. Convection is also the likely dominant heat transfer mechanism in the interiors of the ► [giant planets](#).

Most planets and satellites are thought to be differentiated with the density increasing toward the center (for a recent review on the interior structure of terrestrial planets, see, e.g., Sohl and Schubert 2015 and Sohl et al. 2009). In a terrestrial planet (compare Fig. 1), an Earth-like or rocky satellite such as the ► [Moon](#) or the Jovian satellite ► [Io](#), or a differentiated icy satellite such as ► [Europa](#) and ► [Ganymede](#) (compare Fig. 2), the central region is an iron-rich core. The core is the region where a planetary magnetic field may

Interior Structure, Planetary, Fig. 1 Interior structure of the Earth as a generic model for the interior structure of a terrestrial planet

Interior Structure, Planetary, Fig. 2 Interior structure of Ganymede as a generic model for a differentiated icy satellite

be generated by a dynamo. The core may be layered like in the Earth with a solid inner core and a liquid outer core. Growth of the inner core may release gravitational energy that may power the dynamo.

The core is overlain by the rocky [mantle](#), which, in turn, is overlain by the rocky, mostly basaltic [crust](#). The crust is the product of partial melting and [differentiation](#) of the mantle and is thought to have grown in thickness over time. The mantle and the crust may be chemically layered with discontinuities in density and other material properties. There may, in addition, be discontinuities caused by solid-state phase change boundaries. It is further possible that regions of the mantle are partially molten causing an asthenosphere.

The core radius of the [Earth](#) is very well known from the inversion of geophysical data to be 3485 km on average. The thickness of the crust is up to a few kilometers in oceanic regions and a few tens of kilometers in continental areas. [Venus's](#) interior structure is much less well known with a core radius of probably $0.5 R_P$,

where R_P is the planetary radius, and a basaltic crust of between 20 and 50 km average thickness.

► [Mars's](#) core is also about $0.5 R_P$ in radius and its average crust thickness is between 30 and 80 km.

► [Mercury's](#) core radius is about $0.8 R_P$ and the crust thickness is estimated to be 20–50 km. Sohl et al. 2009 give a compilation of interior models of terrestrial planets, satellites, and icy satellites.

The above generic model also applies to the Moon whose iron-rich core should be small, comprising only 0.3 planetary radii R_P (see Weber et al. 2011) and Io with a core radius of about $0.5 R_P$. The average lunar crust thickness is 30–43 km and varies between 67 km underneath the farside and close to zero underneath the South Pole–Aitken basin (Wieczorek 2015). Other large differentiated satellites such as Ganymede and Europa may have ice shells above their [rock](#) mantles and iron-rich cores (see, e.g., Hussmann et al. 2007 and Sohl et al. 2009). The ice shell on Ganymede may be about 700–900 km thick, while on Europa a thickness of about 150 km is likely. The iron core radius for Ganymede varies between $0.2 R_P$ and $0.3 R_P$ depending on model details, while for Europa the core radius varies between $0.3 R_P$ and $0.6 R_P$. The Jovian satellite [Callisto](#) and the Saturnian satellite [Titan](#) are believed to be incompletely differentiated, with hundreds of kilometers thick ice shells overlying undifferentiated ice/rock/iron cores.

The giant planets [Jupiter](#) and [Saturn](#) have a molecular gaseous atmosphere underlain by a molecular layer of mostly hydrogen and helium (see Fig. 3 and, e.g., Guillot and Gautier 2015 for a review). At a pressure of 0.5 TPa, hydrogen becomes metallic, the transition pressure depending to some extent on temperature. In Jupiter this transition occurs at about $0.75 R_P$; in Saturn the transition occurs at $0.45 R_P$. At the center of these planets, there is a core with a mass of up to ten Earth masses and $0.2 R_P$ radius composed of heavier elements like iron, silicon, and magnesium but also of [water](#), [ammonia](#), and [methane](#). The latter are sometimes termed the planetary ices regardless of whether they are in a solid, liquid, or gaseous state.

The interiors of [Uranus](#) and [Neptune](#) are also thought of as layered, although the transitions

Interior Structure, Planetary, Fig. 3 Interior structure of Jupiter as a generic model for the interior structure of a giant planet

between the layers should be more gradual (see, e.g., Guillot and Gautier 2015). In these models, the outer layer extending down from 0.8 to 0.9 R_P consists of mostly molecular H and He but also of water, ammonia, and methane. The shell below is composed of ice plus little H and He, and there is a rock/iron plus ice core component of a few Earth masses.

Knowledge about the interior structure is derived by using the gravity and magnetic fields of a planet or satellite, its shape, and the propagation of elastic waves through the interior of the body. The latter is the basis of seismology, which is the best method provided one can have seismometers operating on the surface of a planet that is sufficiently seismically active. A similar method uses global oscillations of a giant planet and requires that the oscillations can be observed with telescopes or from satellites. In addition, an equation of state is needed to relate density to pressure and temperature. The parameters in the equation of state need to be determined through laboratory experiments. For the Earth gravity, magnetic and seismic data have been inverted to provide detailed models of the interior structure

that even include lateral variations of density and elastic properties.

The shape of a gravitational equipotential surface about a planet will reflect the distribution of mass in its interior (see, e.g., Wieczorek 2015 for a review). An equipotential surface can be traced by Doppler tracking of an orbiting spacecraft. For a rotating, rotationally symmetric model planet in ► [hydrostatic equilibrium](#), the shape of an equipotential surface will be a flattened spheroid of rotation (one of which will coincide with the physical surface, if in perfect equilibrium). The gravitational potential $V(r, \theta)$ can be expanded in a series of Legendre polynomials with

$$V(r, \theta) = G \frac{m}{r} \left(1 - \sum_{n=2}^{\infty} \left[\left(\frac{R_p}{r} \right)^n J_n P_n(\cos \theta) \right] \right) + \sum_{n=2}^{\infty} \sum_{m=1}^{\infty} \left(\frac{R_p}{r} \right)^n (C_{nm} \cos m\lambda + S_{nm} \sin m\lambda) \times P_{nm}(\cos \theta),$$

where r is the distance to the observer from the center of the planet, θ is the planetocentric polar angle (measured from the pole such that $\theta = 90^\circ$ at the equator), λ is the longitude, G is the universal gravitational constant, m is the planet's mass, and R_p is the average radius. The J_n , C_{nm} , and S_{nm} are coefficients and $P_n(\cos \theta)$ and $P_{nm}(\cos \theta)$ are Legendre polynomials and associated Legendre polynomials, respectively (for an introduction to spherical harmonic functions for geophysical applications, see Stacey and Davis 2008). The coefficients J_n , C_{nm} , and S_{nm} measure the mass distribution in the planet. In particular,

$$mR^2 P_2 J_2 = C - A,$$

where C is the moment of inertia of the planet about the rotation axis and A is the average moment of inertia about an axis in the equatorial plane. The flattening f of the planet depends on J_2 and the rotation rate via

$$f = \frac{3}{2} J_2 + \frac{1}{2} \psi$$

with

$$\psi \equiv \frac{\omega^2 R_P^2}{Gm}.$$

For a constant density body $C/mR_P^2 = 0.4$, $J_2 = \frac{1}{2}\psi$ and $f = \frac{5}{4}\psi$. The latter is the maximum value of the flattening for a given value of ψ . With an increasing concentration of mass toward the center, C/mR_P^2 will become smaller than 0.4, and the flattening will decrease as well.

While the low-order terms are used to constrain the deep interior structure – degree 2 for the terrestrial and degrees 2–6 for the giant planets that are closer to hydrostatic equilibrium – high-order terms can be used to constrain density variations closer to the surface such as thickness variations of the planetary crust. It must be noted that any interpretation of the gravity field is fraught with nonuniqueness problems. The reason is that for the same gravitational force or potential at the location of an observer, mass can be traded against distance. Therefore, interior models based on the gravity field need additional constraints. For Mars the chemistry of the ► [SNC meteorites](#) together with the assumption of an overall chondritic composition of the planet has been used to constrain the core radius. The variation of the thickness of the Martian crust has been derived from the ► [Mars Global Surveyor](#) gravity data and the assumption of a constant crust density.

The magnetic field recorded at a planet or satellite provides additional constraints on the properties of the interior. A near-dipole-shaped magnetic field usually indicates a dynamo and that electrical currents are flowing deep in the interior. The closer the field geometry resembles a dipole, the deeper the source region of the field usually is to be expected. The Earth's magnetic field is understood as being produced in its outer core. The Earth's outer core must therefore be electrically conductive and fluid to allow for dynamo action. That the Earth's outer core is liquid is proven beyond any doubt by the absence of seismic shear waves propagating through that layer. Through analogy it is concluded that there must be at least a liquid outer

core shell in Mercury, the only other terrestrial planet that presently produces a magnetic field. The remnant magnetization of the Martian crust (see, e.g., Connerney et al. 2004) suggests that this planet once produced a magnetic field and that – again – at least an outer core layer was liquid. More evolved modeling of the planet suggests that the entire core is fluid, even today.

The magnetic fields of Jupiter and Saturn are thought to be generated in the metallic hydrogen shells, again allowing for electric currents to flow and dynamo action. The fields of Uranus and Neptune are thought to be produced in ionic oceans relatively close to their surfaces. This is consistent with the observation that their magnetic fields are rich in higher-order terms.

Periodically varying magnetic signals have been recorded at Europa, Ganymede, and Callisto by the ► [Galileo spacecraft](#). The orbits of all three satellites lie within the giant ► [magnetosphere](#) of Jupiter, and the signals at Europa and Callisto have been found to vary with their orbital period. Ganymede has a static dipole magnetic field superimposed with a weak time variable field. Hence, it has been concluded that there must be an electrically conducting layer in the interiors where a magnetic field can be induced as the satellites move through the global magnetic field of their primary. Since the satellites have ice shells and salty water is a good electric conductor, the magnetic signals have been taken as evidence of oceans in these satellites. Moreover, the static field of Ganymede suggests that it too has a partly fluid iron core.

Little is known about the interior structures of the many small satellites and ► [Kuiper belt](#) objects in the outer ► [solar system](#). Gravity data taken from ► [Cassini](#) flybys at the Saturnian satellites have been interpreted to suggest that ► [Rhea](#) may be differentiated. Interpretation of these data does rely on the assumption of equilibrium, which becomes even more questionable for small satellites.

The about 500 exoplanets detected to date suggest that there may be planets that differ from the ones found in our solar system. Even if the three chemical components of our planets,

gas (H, He), ice (H₂O, NH₃, CH₄), and rock/iron were universally representative, the relative proportions may differ. Thus there may be Super-Ganymedes or Sub-Jupiters (e.g., Stevenson 2004). ► [Transit](#) observations and ► [radial velocity](#) observations allow the masses and radii of these planets to be measured. With these and mass-radius relations, the interior structure of these planets can be estimated. Of course, these models do have even more severe uniqueness problems than models of the interior structure of the planets in our solar system. Major difficulties lie with the unknown equations of state of degenerate matter at extremely high pressures and temperatures and the unknown volumes of potential ultra high pressure phases of solids. The difficulties may be more severe for Super-Earths than for large gaseous planets, since Jupiter is close to the maximum radius of an H-He sphere anyway.

Definition

The International Space Station (ISS) is orbiting the Earth at an altitude between 335 and 460 km in an orbital plane inclined by 51.8°. The assembly of this internationally developed research facility began in 1998 with the Russian module Zarya, to be almost completed in 2011. The ISS is the result of the merging of former projects in an international effort including Russia, the United States of America, Europe, Japan, and Canada. The inter-governmental agreement is planning operations until at least 2020 and now extended to 2028. The orbital complex has been permanently occupied since November 2, 2000, and since May 2009 the ISS has the capability to host simultaneously up to six astronauts or cosmonauts. The astrobiology interest of the ISS includes functioning as the permanent base for long-lasting experiments. Scientists have the opportunity to expose directly to space radiations, for several months or more, samples in facilities attached to external payload supports as Bartolomeo on Columbus (European module), the external wall of Zarya (Figs. 1 and 2) (Russian core module), on the exposure facility of Kibo (Japanese Module).

The ISS was completed within around 10 years. It is composed of various pieces: trusses, arms, docking modules, solar panels, experimental modules, and so on. The main modules are: Zarya (Russia 1998), Zvezda (Russia, 2000), Destiny (USA, 2001), Harmony (2003, USA), Columbus (2008, ESA), Kibo -Japanese Experient Module- (2008, Japan), Tranquility (2010, USA), Leonardo (USA, 2011), Bigelow Expandable Activity Module (private-2016, USA), and Nauka (2021 Russia).

The servicing with cargo spacecrafts rely in 2022 on Dragon 2 (Space X), Cygnus (Northrop Grumman Innovation Systems); two commercial companies, and on the Russian Progress spacecraft. The former European ATV and Japanese HTV are no longer in use.

After the retirement of the NASA Shuttle in early 2011, for a while, the expeditions to the ISS were relying only upon the Russian Soyuz spacecraft. Since November 15th, 2020, Dragon

crewed capsules (Space X) are also able to carry 4 astronaut to the ISS. These spacecrafts are launched from the Kennedy Space Center in Florida (USA). Soyuz continues to launch crew from the Russian spaceport, Baikonur in Kazakhstan.

Interplanetary Dust Particle

William M. Irvine
University of Massachusetts, Amherst, MA,
USA

Keywords

Dust, interplanetary · Zodiacal light ·
Gegenschein · Comet · Isotopic anomalies

Synonyms

[Brownlee particle](#); [IDP](#)

Definition

In addition to the Sun; the planets plus their satellites; smaller bodies including asteroids, comets, and meteoroids; and ► [Kuiper belt](#) objects, the roughly defined plane of the solar system contains gas and dust, referred to as the interplanetary medium. The dust grains are, naturally, called interplanetary dust particles, although that nomenclature (and particularly the abbreviation IDPs) is often used to designate particles of presumed interplanetary origin collected on the Earth, primarily in the stratosphere but also from Antarctic and Greenland ice. In the interplanetary medium, sunlight scattered by the dust is responsible for the phenomena of the zodiacal light (the “false morning” of poets, including Omar Khayyam) and the gegenschein (a very faint glow in the antisolar direction). In addition, interplanetary dust particles produce meteors (“shooting stars”) when they strike the Earth’s atmosphere and are incinerated as a result of friction.

Overview

Because these small particles tend over time to be either expelled from the solar system by radiation pressure or to fall into the Sun as a result of ► [Poynting-Robertson drag](#), there must be sources to replenish them. These sources are thought to be collisions among asteroids and Kuiper belt objects, and the release of particles trapped in cometary ices as the comets approach the Sun and the ices sublimate. These sources are confirmed by the ► [Infrared Astronomical Satellite](#) (IRAS) observations of dust bands in the asteroid belt and by meteor showers that are dynamically related to the orbits of comets.

The laboratory study of IDPs began in 1978 when D. Brownlee, using an ex-CIA high-altitude U2 spy plane, collected particles in the stratosphere whose extraterrestrial origin was confirmed by the presence of cosmic ray tracks and isotopic anomalies, particularly deuterium enhancements. Interplanetary particles with

diameters approximately in the range 1–100 μm are slowed sufficiently by friction to survive atmospheric entry; in fact, the Earth is estimated to accrete some 4×10^7 kg of such material annually, and this influx was certainly much greater early in the history of the solar system. The IDPs are composed predominantly of silicates, but there is also up to about 10% by mass of carbon, together with other minerals such as sulfides and magnetite. Evidence for solid carbonaceous compounds (such as ► [HCN polymers](#)) that progressively evaporate with decreasing solar distance in the interplanetary medium, at least in the 1.5–0.3 AU range, confirm that IDPs might have significantly contributed to the enrichment of the telluric planets in organics during the LHB (► [Late Heavy Bombardment](#)) epoch. The so-called anhydrous cluster IDPs appear to be the least processed of these particles reaching the Earth, and they are usually thought to have a cometary origin. Their highly porous structure increases their deceleration and heat transfer in planetary atmospheres, and thus favors the survival of carbonaceous compounds reaching the Earth. These presumably cometary IDPs seem to contain preserved interstellar material, including ► [GEMs](#) and organic material with significant isotopic anomalies relative to terrestrial values, for example, in D/H and $^{15}\text{N}/^{14}\text{N}$. IDPs have also been collected in space by the ► [Stardust](#) mission to comet 81P/Wild 2 and by experiments on the International Space Station. The analysis of the organic matter in IDPs is a very active subject of current research.

[Interstellar chemistry](#)

Definition

Interstellar chemical processes manipulate matter by either creating or destroying molecular material. These processes, acting on gas and dust, include heating, irradiation, shocks, and ► [cosmic ray](#) bombardment, as well as chemical reactions such as ► [ion-neutral](#) and ► [neutral-neutral](#) reactions and surface chemistry.

Overview

All interstellar material is cycled during various phases of stellar life (Fig. 1): from the diffuse medium, to the formation of a star and planetary system, to stellar death. The molecular complexity that arises during each phase can be attributed to the physical and chemical processes that dominate the various environments. In general, the chemistry found throughout the ► [interstellar medium](#) (ISM) involves low densities and extreme temperatures with respect to Earth and varies due to the range of physical conditions found in specific environments. These environments can be divided into distinct regions, based primarily on temperature and density (see Table 1).

In the diffuse interstellar medium (ISM), where densities ($1\text{--}100\text{ cm}^{-3}$) and temperatures ($\sim 100\text{ K}$) are low, the chemistry is dictated by the large flux of ultraviolet radiation coming from nearby stars. The growth of molecular complexity in these regions is minimal due to the limited stability of larger organic species in the presence of an ultraviolet (UV) field. Nonetheless, ► [polycyclic](#) aromatic hydrocarbons (PAHs) do thrive in these harsh conditions and are ubiquitous throughout the ISM (see review by Peeters). On the other hand, ► [dense clouds](#), the cold, dense molecular regions of the ISM, tend to have a much richer chemistry. In these clouds, external UV radiation is insignificant in the inner regions, and cosmic rays are the dominant radiation source creating ions and electrons, as well as providing a source of heating. Within these dark clouds, not only does gas-phase chemistry play a key role, but grains and surface chemistry are also important. The molecular inventory of each region helps

delineate the chemical processes that occur throughout the ISM and how they influence the cycle of material from stellar birth to death.

Basic Methodology

The methods by which interstellar processes are studied typically involve high-resolution spectral

line observations and maps of molecular emission that trace different regions and/or processes that may be occurring (e.g., Evans 1999). Molecules have rotational and vibrational motions coupled to electronic states, all of which are quantized. Molecular transitions are characterized by their energy as either electronic (~ 4 eV; 10^4 K), vibrational (~ 0.1 eV; 1000 K), or rotational (~ 0.01 eV; ≤ 100 K) (see Fig. 2). The visible and ultraviolet

Interstellar Chemical Processes, Fig. 2 Molecular energy levels (in electron volts and wavenumbers)

wavelengths are typically associated with electronic transitions, the infrared traces mostly vibrations, and millimeter/submillimeter wavelengths are dominated by rotational transitions. The large range of temperatures and densities throughout the ISM has led to the detection of numerous species at multiple wavelengths (see ► [Molecules in Space](#); or the CDMS web site at <http://www.astro.uni-koeln.de/cdms/molecules>). All of the ~150 identified interstellar species are just minor constituents of the molecular material, which is dominated by H₂ in dense regions. As can be noted from Table 1, most of the molecular material and the atomic cold neutral medium are traced by low-temperature, rotational transitions at millimeter/submillimeter wavelengths. Spectra obtained for simple, closed-shell (no unpaired electrons), neutral (no charge), diatomic species are simple, having one feature, or line, per rotational transition. This clean spectrum rapidly becomes quite complex when asymmetry, charge, and/or unpaired electrons are present. A detailed review of ► [spectroscopy](#) and analysis at these wavelengths can be found in Townes and Schawlow (1955). The following will be a brief overview of the various interstellar processes that occur in various regions of the ISM and are used to examine the chemistry and physical conditions.

Gas-Phase Chemistry

Matter expelled from stellar atmospheres, particularly older stars, is in the form of molecules and dust. Most species tend to not survive the harsh

conditions of the ISM and are photodissociated or fragmented into smaller molecules. Some species will remain in molecular form and become part of the natal material for new stars in diffuse and ► [molecular clouds](#). In molecular clouds, significant chemistry will occur due to the higher densities and protection from external destructive UV photons. Numerous chemical models have been developed to simulate the chemistry that occurs throughout stellar evolution (see Millar 2006 and references therein). Most of these models employ large chemical networks involving over 5000 reactions and hundreds of atoms and molecules. Most of these reactions are found in either the UMIST Database for Astrochemistry 06 database (Woodall et al. 2007; <http://www.udfa.net/>) or the Ohio State site (Herbst and Wakelam 2008; <http://www.physics.ohio-state.edu/~eric/research.html>).

The ISM is very diffuse with respect to terrestrial densities. Even the “dense” protostellar cores are rarified compared to the Earth’s atmosphere. In these low-density environments, typically only two-body collisions can occur. Temperatures vary from tens to thousands of Kelvin. UV and EUV radiation from nearby stars also plays a key role in the chemistry that occurs throughout the Galaxy.

Photochemistry

Regions within the ISM that have a strong UV field from nearby hot massive (OB) stars or the general interstellar radiation field are known as ► [photodissociation](#) regions (PDRs). The chemistry of PDRs is dominated by the formation and destruction of H₂ (Hollenbach and Tielens 1999). Electron recombination reactions combined with charge transfer help maintain the ionization balance (see Table 2). ► [Photoionization](#) and photodissociation drive additional chemistry. The extent of chemistry that may occur in these objects depends on the gas density and pressure, intensity of the incident radiation field, dust scattering, and elemental abundances (Sternberg and Dalgarno 1995).

PDRs have distinguishable molecular regions, dependent on the ► [optical depth](#) of the source from the radiation field. The most exposed region contains atomic hydrogen, helium, oxygen, and ionized carbon and generally a higher temperature

Interstellar Chemical Processes, Table 2 Reaction categories

Reaction	Example
Ion-neutral	$\text{H}_3^+ + \text{O} \rightarrow \text{H}_2\text{O}^+ + \text{H}$
Neutral-neutral	$\text{OH} + \text{H}_2 \rightarrow \text{H}_2\text{O} + \text{H}$
Photoionization	$\text{H}_2\text{O} + h\nu \rightarrow \text{H}_2\text{O}^+ + e^-$
Photodissociation	$\text{H}_2\text{O} + h\nu \rightarrow \text{OH} + \text{H}$
Photodetachment	$\text{C}_6\text{H}^- + h\nu \rightarrow \text{C}_6\text{H} + e^-$
Radiative association	$\text{H}_2 + \text{S}^+ \rightarrow \text{H}_2\text{S}^+ + h\nu$
Dissociative recombination	$\text{H}_3\text{O}^+ + e^- \rightarrow \text{H}_2\text{O} + \text{H}$
Associative detachment	$\text{C}_6\text{H}^- + \text{H} \rightarrow \text{C}_6\text{H}_2 + e^-$

Adapted from Bergin (2009). Rates for reactions can be found on the UMIST database (<http://www.udfa.net/>) by Woodall et al. (2007). $h\nu$ represents a photon

(~100–1000 K). The next region is defined by the formation of molecular hydrogen (H_2), but carbon is still in its ionized form. In more shielded regions, carbon is converted into the molecular form of CO, and temperatures are lowered (~10–100 K) due to rotational emission from this molecule.

Photochemistry also plays a key role on ► [interstellar grains and ices](#). This is briefly discussed below.

Ion-Neutral Chemistry

Interstellar chemistry is highly influenced by the low temperatures, which require exothermic reactions, and the low densities that restrict these reactions to mostly two bodies. Reactions that involve ions, either positively or negatively charged species, typically meet the exothermic requirement and tend to dominate interstellar gas-phase chemistry (e.g., Herbst and Klemperer 1973). The formation of positive ions in the ISM is highly dependent on ► [cosmic ray](#) (CR) bombardment. Ionization of H_2 , via this process, to produce H_3^+ drives most ion-neutral chemistry in dense regions, leading to a variety of complex ions (Bergin 2009). These newly formed ions then typically undergo dissociative recombination (see Table 2) to form less protonated neutral fragments. Radiative association with H_2 does occur, though these reactions tend to be much slower (Herbst and van Dishoeck 2009).

At low temperatures, ► [ion-neutral reactions](#) may also influence interstellar isotope enrichments,

known as fractionation, due to small differences in the zero-point vibration energies. This is most commonly observed via the deuterium exchange reaction with H_3^+ , where HD is favored over H_2 :

H_2D^+ will then fractionate other species by deuterium transfer reactions.

Other isotope exchange reactions, mostly ion neutral, are also quite significant in the ISM and can enhance abundance ratios to extreme values. These mechanisms are typically of the form

The reverse reaction barely proceeds at low temperatures, thereby enhancing one isotopologue, ^{13}CO in this case, in cold regions (e.g., Langer et al. 1984).

Neutral-Neutral Chemistry

The interaction between two uncharged species, or ► [neutral-neutral reactions](#), also plays a role in interstellar chemistry. These reactions are typically endothermic with high activation barriers for the interaction between two nonradicals (species bearing no unpaired electrons). These reactions are insignificant in cold, diffuse interstellar chemistry. However, the presence of a radical or an atom can significantly lower the barrier, and such reactions then become important to the formation and destruction of molecules (Smith et al. 2004). Reactions involving radicals still have a limited number of experimental studies, though a few have been tested at low temperatures and have proven the current theories (Smith et al. 2006; Sabbah et al. 2007; review by Smith).

Anions

The recent discovery of ► [anions](#), negatively charged species, in the ISM and in circumstellar envelopes has expanded the gas-phase molecular processes typically considered in these environments. The formation of these negative ions is by radiative association of an electron to a neutral parent species, which is fairly efficient for precursors with large electron affinities (Herbst and

Osamura 2008), or through dissociative recombination of a neutral and electron. Anions are considered to be readily destroyed by three mechanisms: associative detachment, ion-neutral reactions, and photodetachment (Table 2 and Herbst and van Dishoeck 2009).

Recently, models of interstellar chemistry have incorporated anion chemistry and have found consistency with observed abundances in the ISM (Millar et al. 2007). These studies have verified the enhanced abundances of larger (long-chain) anions compared to their shorter counterparts. This is due to the radiative association rate increase with the number of atoms (Roueff and Herbst 2009). However, these processes have only limited experimental data.

Shocks

The interstellar plasma is highly compressible, and wave motions can easily exceed characteristic signal speeds leading to the formation of either hydrodynamic or magnetohydrodynamic (MHD) shocks, depending on the magnetic field strength. The former have been classified as J-type (jump), or J-shocks, in which physical flow variables (e.g., density and temperature) undergo a discontinuous jump at the shock front. The latter case gives rise, in weakly ionized plasma, to C-shocks where the neutral and (ion-electron) plasma components behave as individual fluids and in which the flow variables are continuous (see ► [Shock, Interstellar](#)).

The principal chemical effects in shocked gas arise from the elevated gas temperatures. Temperatures in the range ~ 1000 – 4000 K can drive endothermic reactions and exothermic processes possessing activation-energy barriers. In multi-fluid MHD C-shocks, the relative streaming motion between the ion-electron plasma and the neutral fluid imparts additional energy into endoergic ion-molecule reactions.

Shock chemistry thus opens up molecular formation and destruction pathways that are not accessible in cold pre-shock gas leading, for example, to high abundances of sulfur-bearing molecules. Particularly important are reactions with H_2 , as in the reaction sequence that converts oxygen atoms into hydroxyl and then into water

molecules in shock waves around newly formed stars. Apart from allowing new high-temperature pathways for two-body molecular chemistry in the post-shock gas, strong shocks produce a UV radiation field that can initiate photochemistry both upstream and downstream of the shock front.

An important chemical process involving interstellar shock waves is dust processing. Refractory dust particles coated by molecular ices can be efficiently sputtered by high-energy collisions with gaseous atoms and molecules. This leads to the removal of the icy mantles and consequently high abundances of the constituent molecules in the gas (e.g., methanol). At higher shock speeds, the refractory core itself is sputtered, and this is the origin of the pronounced ► [SiO](#) emission observed in the outflows and winds from young protostars.

Surface Chemistry

Dust and grains formed in the outflows of evolved stars are dispersed throughout the ISM. At low temperatures, atoms and small molecules will collide with and/or adhere to the surface of these grains, forming an ice layer. The formation of some molecules on the surfaces of grains, particularly hydrogenated species that are subsequently ejected into the gas phase, is a significant process for interstellar chemistry (van Dishoeck and Blake 1998). There are three major theories explaining surface reactions in interstellar grains: ► [Langmuir-Hinshelwood](#), hot atom, and ► [Eley-Rideal](#) (Fig. 3). Small molecules or atoms will accrete onto a binding site of a molecular surface with some amount of efficiency. They can then react with an atom or a molecule already on the grain, and the product can desorb by either thermal evaporation (sublimation) or various other nonthermal processes (Herbst and van Dishoeck 2009).

Such gas-grain processes dominate the formation of molecular hydrogen (H_2), which is not efficiently formed by two-body collisions in the gas. However, due to our limited knowledge of the composition and structure of interstellar grains, the exact formation mechanism of H_2 is not understood, regardless of numerous theoretical and experimental studies (e.g., Cazaux and Tielens

Interstellar Chemical Processes, Fig. 3 Grain-surface reactions mechanisms

2002, 2004, 2010; Habart et al. 2004; Pirronello et al. 1997, 1999, among others). Surface processes are also considered to be the dominant method for hydrogenation of C, O, N, and S forming CH_4 , H_2O , NH_3 , and H_2S , respectively (Wooden et al. 2004). CO also follows the same process once accreted onto a surface to produce CH_3OH (Charnley et al. 1997).

Radiation Effects

Icy grain mantles are observed throughout the ISM and are subjected to ultraviolet radiation, cosmic rays, and temperature variations that will alter the surface composition (e.g., Bernstein et al. 1995; Moore and Hudson 1998). Such effects as amorphization, formation of residues, ► **sputtering**, and surface chemistry are produced (Hudson and Moore 2001). Most observed interstellar ices are composed of H_2O , CH_3OH , NH_3 , CO, and CO_2 though they likely bear other minor constituents not detectable at trace concentrations beneath the strong infrared bands of the simple species (e.g., Gibb et al. 2000). These simple ice mixtures may then be exposed to external radiation (UV photons or cosmic rays), which will either sputter simple species from the mantle or stimulate molecular reactions to occur, and products will desorb (Fig. 4; see ► **Photodesorption**). Photolysis of interstellar ices will produce radicals and ions that react on the surface as well as during heating events. Numerous experiments have been conducted to gain further understanding of these reactions upon exposure to UV photons and H^+ irradiation (radiolysis). Particular focus has been

Interstellar Chemical Processes, Fig. 4 Illustration of the makeup of an icy dust grain in the ISM and the typical energetic processes to which it is exposed. (From Fraser et al. 2002)

toward the hydrogenation reactions of CO ices, typically mixed with H_2O , in forming CH_3OH in observed quantities (e.g., d'Hendecourt et al. 1986; Watanabe et al. 2003; Hudson and Moore 1999). However, these experimental yields are not fully consistent with observed abundances in the ISM.

Ice-grain photolysis chemistry has received much attention for its astrobiological implications. Multiple studies have been conducted on the formation of prebiotic species including

amino acids, nucleobases, amphiphiles, etc. (e.g., Bernstein et al. 2002; Nuevo et al. 2009; Dworkin et al. 2001). These studies suggest that prebiotic compounds are readily produced by energetic processing of interstellar ices and may therefore be ubiquitous throughout the ISM.

Interstellar Dust

Douglas Whittet

Department of Physics, Applied Physics and Astronomy, Rensselaer Polytechnic Institute, Troy, NY, USA

Keywords

Absorption · Astrochemistry · Chemical reactions · Infrared radiation · Interstellar medium · Polarization · Scattering · Solid particles · Substrate

Synonyms

[Cosmic dust](#); [Interstellar grains](#); [Interstellar particles](#)

Definition

Interstellar dust consists of small solid particles with sizes in the nanometer to micrometer range, accounting for approximately 1% of the total mass of the ► [interstellar medium](#). The particles are generally thought to be composed of a mixture of silicates and solid carbon (amorphous or graphitic carbon, aliphatic or aromatic hydrocarbons, and possibly kerogen-like organic material). They are responsible for the extinction and polarization of starlight and for ► [scattering](#) that produces ► [reflection nebulae](#) around dust-embedded stars; they also act as efficient radiators in the infrared, providing an important cooling mechanism for interstellar clouds and protostellar envelopes. The surfaces of dust grains provide a substrate for important chemical surface reactions.

History

The earliest evidence for the presence of dust in the interstellar medium was provided in the late nineteenth and early twentieth centuries by photographic images of dark nebulae, such as those reported by E. E. Barnard in his *Atlas of the Milky Way*, and by studies of the distribution and colors of stars by Wilhelm Struve, Jacobus Kapteyn, Robert Trumpler, and others (see Whittet 2022 for a review). It was found that the apparent number of stars per unit volume of space shows an anomalous decline with distance from the Sun unless it is assumed that starlight is dimmed by extinction in proportion to the distance traveled. The dust was also shown to redden starlight. Much subsequent work in the mid-twentieth century on the optical properties of the dust was motivated by the desire to correct data for its presence rather than by an intrinsic interest in the phenomenon. In more recent times, dust has been recognized as a vital and active ingredient of the interstellar medium and as a primary carrier of the elements needed to make planets and life in solar systems.

Overview

Studies of interstellar dust are aimed at understanding its role in physical and chemical processes that are of great importance in astrophysics, astrochemistry, and astrobiology. Dust is a vital ingredient of the molecular universe: It provides the raw materials for the origins of planets and compounds essential to the origins of planetary life. Techniques used to investigate its properties include telescopic observations across the electromagnetic spectrum, mathematical modeling, and laboratory studies of primitive solar-system materials and interstellar analogs.

Basic Methodology

The study of interstellar dust involves astronomical observation over a wide range of wavelength, interpreted with the aid of mathematical modeling and laboratory data (e.g., Mathis 1996; Draine 2003; Witt et al. 2004; Whittet 2022). The primary observational phenomena arising from dust are extinction, polarization, and infrared emission. Extinction is the combination of two physical phenomena: absorption (whereby photons are removed from a transmitted beam and their energy is converted to internal kinetic energy of the particle) and scattering (whereby photons are deflected from the transmitted beam). Scattering is primarily responsible for the reddening of starlight by selective removal of blue light from the transmitted beam, and scattered light is observed directly as bluish reflection nebulae in the vicinity of dust-embedded stars and as a weak background (the diffuse galactic light). The absorptive component of extinction may produce discrete spectral features, including a broad, strong absorption “bump” centered at 217 nm in the ultraviolet, and various features associated with vibrational modes of solids in the infrared. For grains in thermal equilibrium, the balance of energy absorbed at shorter wavelengths is reemitted in the mid-to-far infrared. The spectral energy distribution of this emission provides basic information on the temperature and optical properties of the

dust grains. The intensity of the emission also provides a means of estimating the total mass of an interstellar cloud or prestellar core. The smallest (nano-sized) interstellar particles undergo substantial transient heating on absorption of individual energetic photons, causing them to exhibit both line and continuum emission in the near-to-mid infrared. The interaction of dust with radiation also results in polarization. This is observed in starlight, in scattered radiation produced by reflection nebulae, and in infrared radiation emitted by the dust. Polarization phenomena are generally attributed to nonspherical (flattened or elongated) particles that are partially aligned by the presence of ► [magnetic fields](#). Other methods used to study interstellar dust include gas-phase abundance measurements for chemical elements that may be adsorbed onto dust (Whittet 2010, 2022) and laboratory investigations of presolar grains in primitive meteorites (Nittler and Ciesla 2016).

Key Research Findings

The efficiency of the interaction between radiation and a solid particle is optimized when the dimensions of the particle are of the same order as the wavelength of the radiation. Because of this, spectral variations in interstellar extinction and polarization are highly sensitive to particle size. The observations show that particles with dimensions in the nanometer to micrometer range are present in the interstellar medium. Small particles greatly outnumber larger ones (the number of particles in a given size interval varies approximately with size to the power -3.5), but the larger particles nevertheless contain the bulk of the total mass. Dust has been shown to contain virtually all of the interstellar endowment of the abundant planet-building chemical elements Mg, Si, and Fe, together with substantial fractions of the key life elements C and O. In low-density (“diffuse”) regions of interstellar space, the dust is composed primarily of amorphous, anhydrous silicates such as olivine and pyroxene, and of carbon in various forms (amorphous or partially graphitized carbon,

aliphatic or aromatic hydrocarbons, and possibly kerogen-like organic refractory matter). The smallest particles include a variety of ► [polycyclic aromatic hydrocarbons](#) responsible for a characteristic family of spectral emission lines in the infrared (Tielens 2008). The grains exchange material with the interstellar gas: Gas-phase atoms and molecules become attached to the surfaces of the grains and may react there to form new molecules, including ices, which are widely observed in lines of sight that intercept relatively dense molecular clouds. Reactions on the surfaces of dust grains provide the only viable route to formation of H_2 , the most abundant interstellar molecule. The grains are destroyed on timescales of a few 100 million years by energetic shock waves that permeate interstellar space as the result of supernova explosions.

The composition and evolution of interstellar dust in molecular clouds is of particular importance to astrobiology because the dust acts as both a carrier of key chemical elements needed to form planets and life and a crucible for chemical evolution of those elements (Whittet 2017, 2022). Catalytic surface reactions on dust are effective sources of molecules such as H_2O , NH_3 , CH_4 , CH_3OH , $HCOOH$, and H_2CO that are produced much less efficiently by gas-phase reactions. These relatively simple molecules are subsequently processed into more complex prebiotic compounds in regions of star formation. It is not yet clear to what extent such molecules survive the formation of new solar systems such as our own, to become incorporated into planetesimals and delivered to planetary surfaces. However, analyses of the isotopic compositions of meteorites and interplanetary dust particles (including cometary samples returned by the Stardust Mission) indicate that they contain material of exotic (presolar) origin. The high deuterium content of some organic compounds in meteorites is consistent with an origin at cryogenic temperatures in interstellar clouds.

Interstellar dust plays a key role in the physical process of star formation for sunlike stars. Stars are born in dense cores within molecular clouds at initial temperatures of order 10 K. As a

► [protostar](#) begins to collapse, the release of gravitational potential energy causes it to become warmer, and the resulting thermodynamic pressure would halt the contraction in the absence of a mechanism to dissipate heat. Dust grains provide such a mechanism: They are warmed by collisions with the gas and dissipate heat by radiating at far-infrared wavelengths, allowing the collapse to continue.

The radiation field that permeates a region of active star formation is regulated by the presence of dust. The dust attenuates energetic radiation, providing shielded environments in which complex molecules can survive. Warm regions (hot cores and corinos) in which sublimated ice products interact with molecules already present in the gas promote the formation of complex organic molecules (Herbst and van Dishoeck 2009). Modern observational facilities such as the Atacama Large Millimeter/submillimeter Array enable the distribution of these molecules to be studied in protoplanetary disks around young sunlike stars. This interaction of dust and radiation can also lead to the production of significant levels of circular polarization in regions containing luminous protostars, typically as the result of scattering by aligned grains. It has been proposed that ► [photochemistry](#) driven by circularly polarized radiation of a given handedness may lead to chiral selectivity and might explain the observed excess of L-enantiomers in amino acids extracted from carbonaceous meteorites in our solar system (see Whittet 2017 for a review).

Future Directions

Important questions concerning the nature and evolution of interstellar dust and its relevance to astrobiology remain to be answered. Two key projects are summarized here.

The life cycle of dust. Refractory dust grains composed of silicates or carbon are formed by condensation in the ejecta of dying stars such as red giants, red supergiants, and ► [supernovae](#). The grains may undergo growth in the interstellar medium by coagulation or mantle deposition, and

they may be cycled in and out of star-forming regions or destroyed by shocks. The quantitative details of these processes are not yet well understood. Estimates suggest that dust is destroyed more rapidly than it is replenished by stellar ejecta, implying that the bulk of the solid material is formed in the interstellar medium itself (Jones and Nuth 2011). This is facile for ► [interstellar ices](#), which readily condense (and survive) within the confines of molecular clouds, but an interstellar origin is problematical for the refractory dust that persists in harsher environments. The uptake of elemental oxygen into the dust material is also poorly understood, suggesting the existence of a previously unrecognized reservoir such as O-rich carbonaceous solids or ice particles much larger than those typically assumed in grain models (Whittet 2010, 2022). New observations are needed to test the hypothesis that organic refractory matter, formed by energetic processing of the ices in regions of active star formation, is a significant constituent of dust in the general interstellar medium. Future observations of greater sensitivity will be needed, facilitated by the availability of the James Webb Space Telescope, together with new laboratory work on the spectra of analogue materials.

The interstellar endowment of protoplanetary disks. Models for the origin of primitive bodies such as ► [comets](#) and icy planetesimals in our solar system span the range from simple assemblages of interstellar dust and ices to material that has been almost completely reprocessed and recondensed in the solar nebula. Whether interstellar matter has any direct influence on the inventory of life-relevant molecules delivered to planetary surfaces thus remains an open question. Progress toward an answer to this question is likely to result from integration of research activities in several areas: These include astronomical observations of ► [protoplanetary disks](#) around sunlike stars and of comets in our solar system, mathematical modeling of processes in protoplanetary disks, and laboratory analyses of available samples of primitive solar system material, including ► [carbonaceous chondrites](#), interplanetary dust particles, and stardust samples.

Interstellar Dust Spectroscopy

Karine Demyk

Institut de Recherche en Astrophysique et Planétologie, Université de Toulouse, CNRS, CNES, 9 Av. du Colonel Roche, 31028 Toulouse Cedex 4, France

Definition

Spectroscopy is an essential tool to investigate the composition and structure of cosmic matter. To interpret astronomical observations, laboratory astrophysics experiments are built and dedicated to the measurement of the spectroscopic properties of interstellar dust analogs such as silicate and carbonaceous dust and ices. Interstellar dust spectroscopy includes electronic, vibrational, and rotational spectroscopy from the X-ray to the millimeter domain.

Overview

Spectroscopic observations of astrophysical environments have revealed number of spectral features attributed to cosmic dust. These features provide information on the composition and structure of the dust components: silicates, carbonaceous dust, and ices (Demyk 2011). In astrophysical environments, interstellar dust interacts with radiation through absorption and scattering. The interpretation and modeling of

astronomical and planetary observations, which allow to probe the chemical and physical conditions and evolution of the medium, rely on the knowledge of the optical properties of analogs of cosmic dust and of their absorption and scattering cross sections on the broadest spectral range (Andersen et al. 2013).

Measuring these properties is a broad and active field of research motivated by the development of observatories more and more performant in terms of sensitivity, angular and spectral resolution on wider and wider spectral domain (among which ISO, Spitzer, instruments on the VLT and Keck telescopes and in the future JWST, METIS on the ELT, Athena. . .). State-of-the-art experiments have been developed to measure the spectroscopic properties of interstellar dust analogs in conditions as close as possible to the astrophysical and planetary conditions in terms of temperature, pressure, and in terms of sample size, structure, and morphology (Henning and Mutschke 2010; Jäger et al. 2009). To cover the broadest spectral range some of them may be coupled to large infrastructures such as synchrotron sources (for example in the X-ray or in the far-infrared domains). These devices are in most cases also used to study the processing of interstellar dust (for instance submitted to irradiations of high energy photons and particles, to study gas-grain interaction).

Absorption spectroscopic measurements of interstellar dust analogs, such as minerals (silicates and oxides), carbonaceous dust, and ices are generally performed in transmission or in reflection. The study of ices requires experimental devices combining the production of ice thin films with spectroscopic capabilities. Spectroscopic measurements of silicate, oxide, and carbon-based dust analogs are usually performed on bulk, film or powder samples depending on the method of synthesis. Powder samples, which are more representative of interstellar nanograins, are usually dispersed in a solid transparent matrix (KBr, CsI, polyethylene). A lot of experimental work has been devoted to the characterization of the influence of the grain shape, grain size, and of the matrix on the measured spectra, especially on the band shape and position. The very small grains

(VSGs) and the carriers of the aromatic infrared band (AIB), although not very well constrained, are thought to be carbonaceous nanograins or aggregates with sizes ranging from 1 to a few nanometers. In space, their temperature fluctuates on a large range from 10 to more than 2000 K depending on the species. Large polycyclic aromatic hydrocarbons (PAHs) have been proposed to account for the emission in the AIB. Analogs of this dust component are difficult to produce and to study in the gas phase on such a wide range of temperature. Their spectroscopic characterization combines solid-state and gas-phase measurements to theoretical calculations for the species that cannot be studied experimentally (Joblin et al. 1995).

Laboratory spectra of interstellar dust analogs may be directly compared to astrophysical or planetary observations. They are also used to calculate extinction cross sections and optical constants (Gerakines and Hudson 2020; Mutschke 2013). The latter, related to the dielectric function, describe the response of a material submitted to an electromagnetic field. Optical constants make it possible to model the size and shape distribution of cosmic dust which are difficult to reproduce in the lab but which must be taken into account for a good modelling of astrophysical and planetary environments. Spectra, extinction cross sections, and optical constants of interstellar dust analogues are delivered to the scientific community through databases (Mattiola et al. 2020; Mallocci et al. 2007; Schmitt et al. 2018).

Interstellar Filaments

Philippe André

Laboratoire d'Astrophysique (AIM), CEA Paris-Saclay, Gif-sur-Yvette, France

Definition

An interstellar filament may be defined as any elongated structure in the cold ► [interstellar medium](#) which has an aspect ratio larger than ~5–10 and is significantly overdense with respect to its surroundings.

History

The presence of parsec-scale filamentary structures in nearby interstellar clouds and their potential importance for star formation have been pointed out by many authors for more than three decades. For example, Schneider and Elmegreen (1979) discussed the properties of 23 elongated dark nebulae, visible on optical plates and showing evidence of marked condensations or internal globules along their lengths, which they named “globular filaments.”

Overview

Recent studies of the nearest star-forming clouds of the galaxy at submillimeter wavelengths with the *Herschel* Space Observatory have provided us with unprecedented images of the initial conditions and early phases of the star formation process. The *Herschel* images reveal an intricate network of filamentary structures in every interstellar cloud. These filaments all exhibit remarkably similar widths – about a tenth of a parsec – but only the densest ones contain prestellar cores, the seeds of future stars. The *Herschel* results favor a scenario in which interstellar filaments and prestellar cores represent two key steps in the star formation process: first turbulence stirs up the gas, giving rise to a universal weblike structure in the interstellar medium, and then gravity takes over and controls the further fragmentation of filaments into prestellar cores and ultimately ► [protostars](#). This scenario provides new insight into the inefficiency of star formation, the origin of stellar masses, and the global rate of star formation in galaxies. Despite an apparent complexity, global star formation may be governed by relatively simple universal laws from filament to galactic scales.

Basic Methodology

Two main approaches have been used to trace the filamentary structure of the cold interstellar medium: (1) mapping the optically thin far-infrared and submillimeter continuum emission from the cold (~10–30 K) dust contained in the

clouds and (2) mapping the absorption of the local background infrared emission (from warmer cloud dust or remote stars) by the same cold dust component in the clouds. Mapping the molecular gas component is generally less effective in this respect as most molecules tend to freeze out onto dust grains in the dense, cold inner parts of molecular clouds.

Two key advantages of *Herschel* dust continuum imaging observations for studies of interstellar cloud structure have been (1) an unprecedented mapping speed at wavelengths ranging from $\lambda = 160\ \mu\text{m}$ to $\lambda = 500\ \mu\text{m}$ where cold interstellar clouds emit the bulk of their thermal radiation and (2) a very good angular resolution $18''$ (half-power beam width) at $\lambda = 250\ \mu\text{m}$, corresponding to $\sim 0.03\ \text{pc}$ at a distance $d = 350\ \text{pc}$, which is sufficient to resolve the typical Jeans length and thus individual prestellar dense cores in nearby molecular clouds.

Key Research Findings

Omnipresence and Universality of Filamentary Structures in the Cold ISM

The high quality and dynamic range of the *Herschel* images are such that they provide key information on both dense cores on small ($< 0.1\ \text{pc}$)

scales *and* the structure of the parent background cloud on large ($> 1\ \text{pc}$) scales. In particular, one of the most spectacular early findings made with *Herschel* is the ubiquitous presence of long ($> \text{pc}$ scale) filamentary structures in the cold interstellar medium (ISM) (cf. Fig. 1) and the apparently tight connection between the filaments and the formation process of dense cores (e.g., André et al. 2010; Men'shchikov et al. 2010; Molinari et al. 2010). Remarkably, filaments are omnipresent even in diffuse, non-star-forming complexes such as the Polaris translucent cloud (cf. Fig. 2 – Miville-Deschênes et al. 2010; Ward-Thompson et al. 2010). Moreover, in any given cloud complex, the *Herschel* images reveal a whole network of filaments (see Fig. 1), making it possible to characterize their properties in a statistical manner. Detailed analysis of the radial column density profiles derived from *Herschel* data shows that interstellar filaments are characterized by a very narrow distribution of central widths with a typical FWHM value of $\sim 0.1\ \text{pc}$ (Arzoumanian et al. 2011, 2019). A plausible interpretation of this common width of filaments is that it corresponds to the sonic scale below which interstellar turbulence becomes subsonic in diffuse, nonstar-forming gas (cf. Padoan et al. 2001; Federrath 2016).

The Key Role of Interstellar Filaments in the Star Formation Process

The observed correspondence between the filaments and the spatial distribution of compact cores is also remarkable (see Fig. 3), suggesting that *dense cores form primarily along filaments*. More precisely, the prestellar cores identified with *Herschel* are preferentially found within the *densest filaments* with masses per unit length exceeding $16 M_{\odot}/\text{pc}$ and column densities exceeding $\sim 7 \times 10^{21} \text{ cm}^{-2}$ (Könyves et al. 2015 and Fig. 3). In the Aquila region, for instance, the distribution of background cloud column densities of the prestellar cores shows a steep rise above $N_{\text{H}_2, \text{back}} \sim 5 \times 10^{21} \text{ cm}^{-2}$ and is such that $\sim 90\%$ of the candidate-bound H_2 cores are found above a background column density $N_{\text{H}_2, \text{back}} \sim 7 \times 10^{21} \text{ cm}^{-2}$, corresponding to a background visual extinction $A_{V, \text{back}} \sim 8$ (André et al. 2014). The *Herschel* observations of the Aquila Rift complex therefore strongly supports the existence of a column density or visual extinction threshold for the formation of prestellar cores at $A_{V, \text{back}} \sim 5\text{--}10$, which

had been suggested by earlier ground-based studies of, for example, Taurus and Ophiuchus (cf. Onishi et al. 1998; Johnstone et al. 2004). In the Polaris flare, the *Herschel* results are also consistent with such an extinction threshold, since the observed background column densities are all below $A_{V, \text{back}} \sim 8$, and there are no examples of bound prestellar cores in this cloud. Moreover, the *Herschel* results provide an *explanation* of this threshold in terms of the filamentary structure of molecular clouds. Given the characteristic width $\sim 0.1 \text{ pc}$ measured for the filaments (Arzoumanian et al. 2011), the threshold at $A_{V, \text{back}} \sim 8$ or $\Sigma_{\text{back}} \sim 130 M_{\odot} \text{ pc}^{-2}$ corresponds to within a factor of <2 to the critical mass per unit length $M_{\text{line, crit}} = 2 c_s^2 / G \sim 16 M_{\odot}/\text{pc}$ required for the hydrostatic equilibrium of isothermal filaments (cf. Ostriker 1964; Inutsuka and Miyama 1997), where $c_s \sim 0.2 \text{ km/s}$ is the isothermal sound speed for a typical gas temperature $T \sim 10 \text{ K}$. Thus, the core formation threshold approximately corresponds to the *threshold above which interstellar filaments are*

Interstellar Filaments, Fig. 3 *Left:* Column density map of the Aquila star-forming region derived from *Herschel* data (André et al. 2010). The contrast of the filaments has been enhanced by image processing. The filaments which have “supercritical” masses per unit length ($M_{\text{line}} \geq M_{\text{line,crit}}$; see text) and are thus likely gravitationally unstable are

gravitationally unstable. Prestellar cores are mostly observed above this threshold because they form out of a filamentary background and only filaments with transcritical or supercritical masses per unit length ($M_{\text{line}} \geq M_{\text{line,crit}}$) are able to fragment efficiently into self-gravitating cores (cf. André et al. 2010 and Fig. 3).

Toward a Universal Scenario for Star Formation?

The results obtained with *Herschel* in nearby clouds and summarized above provide key insight into the first phases of the star formation process. They emphasize the role of filaments and support a scenario according to which the formation of prestellar cores occurs in two main steps. First, the dissipation of kinetic energy in large-scale magnetohydrodynamic (MHD) turbulent flows generates a whole network of 0.1 pc-wide filaments in the ISM; second, the densest filaments fragment into prestellar cores by gravitational instability above or close to the critical mass per unit length $M_{\text{line,crit}} \approx 16 M_{\odot} \text{ pc}^{-1}$.

The realization that prestellar core formation occurs primarily along gravitationally unstable

highlighted in *white*. Note how the prestellar dense cores identified with *Herschel* (small blue triangles) tend to be concentrated in such “supercritical” filaments. *Right:* Close-up column density map of the area marked by a *yellow box* on the *left*, showing several examples of prestellar cores (See Könyves et al. 2015)

filaments of roughly constant width $W_{\text{fil}} \sim 0.1 \text{ pc}$ may also have implications for our understanding of star formation on global galactic and extragalactic scales. Remarkably, the critical mass per unit length of a filament, $M_{\text{line,crit}} = 2 c_s^2 / G$, depends only on gas temperature (i.e., $T \sim 10 \text{ K}$ for the bulk of molecular clouds, away from the immediate vicinity of massive stars) and is modified by only a factor of order unity for filaments with realistic levels of magnetization (Fiege and Pudritz 2000). This may set a quasi-universal threshold for star formation in the cold ISM of galaxies at $M_{\text{line,crit}} \sim 16 M_{\odot} \text{ pc}^{-1}$ in terms of filament mass per unit length, or $M_{\text{line,crit}} / W_{\text{fil}} \sim 160 M_{\odot} \text{ pc}^{-2}$ in terms of gas surface density, or $M_{\text{line,crit}} / W_{\text{fil}}^2 \sim 1600 M_{\odot} \text{ pc}^{-3}$ in terms of gas density (i.e., a number density $n_{\text{H}_2} \sim 2 \times 10^4 \text{ cm}^{-3}$). Indeed, *Spitzer*-infrared studies of the star formation rate as a function of gas surface density in molecular cloud complexes (e.g., Heiderman et al. 2010; Lada et al. 2010) show that the star formation rate tends to be linearly proportional to the mass of dense gas above a surface density threshold of $\Sigma_{\text{th}} \sim 120\text{--}130 M_{\odot} \text{ pc}^{-2}$ and drops to negligible values below Σ_{th} .

Moreover, essentially, the same relation between the global star formation rate and the total mass of dense gas above the threshold is found in nearby galactic clouds (Lada et al. 2010) and external galaxies (Gao and Solomon 2004). This suggests that there may be a quasi-universal “star formation law” converting the dense molecular gas of self-gravitating filaments into stars above the threshold (Lada et al. 2012; André et al. 2014).

Future Directions

The *Herschel* results on interstellar filaments are very encouraging as they tentatively point to a unified picture of star formation in both galactic molecular clouds and external galaxies. Much more work is needed, however, to understand the detailed fragmentation physics of dense molecular filaments, in particular the origin of their common inner width, and to determine whether the same 0.1 pc width also holds beyond the nearby clouds of Gould’s Belt.

The study of interstellar filaments is becoming a very active research field. Interesting new results on the fragmentation properties of star-forming molecular filaments have been obtained recently with submillimeter interferometers such as ALMA and NOEMA (e.g., Beuther et al. 2015; Kainulainen et al. 2017; Hacar et al. 2018; Shimajiri et al. 2019) and call for modifications to standard linear fragmentation models of quasi-equilibrium cylindrical filaments (cf. Inutsuka and Miyama 1992; Clarke et al. 2017).

Confirming and refining the filament scenario sketched in the previous section will also require extensive follow-up spectroscopic observations to constrain the dynamics of the filaments imaged with *Herschel*, as well as detailed comparisons with numerical simulations of molecular cloud formation and evolution. Recent observations suggest the presence of significant velocity gradients both along and across filaments (e.g., Williams et al. 2018; Dhabal et al. 2018), with a tendency for the transverse velocity gradients to dominate. More systematic studies will be required, however, to draw general conclusions.

Last, but not least, ALMA and NOEMA will be instrumental in testing whether the filament

paradigm is truly universal and applies to both the whole Milky Way beyond Gould’s Belt and the cold ISM of other galaxies.

Definition

Interstellar ice spectroscopy experiments are performed in the laboratory under conditions reproducing, as closely as possible, those in astrophysical environments. The primary aim is the interpretation of observational ice spectra. The majority of observational data on ices are measured in the mid-infrared range (mid-IR, approximately 2.5–25 μm), where molecules absorb light via their vibrational modes. In the laboratory, IR spectrometers are used to record spectra of solid samples of relevant species (e.g., water, carbon dioxide, etc.). The positions, profiles, and intensities of vibrational bands are compared to observational spectra to identify and quantify the molecular composition of astrophysical ices.

Overview

In astrophysical environments that are sufficiently cold and dense, molecules accumulate in icy layers covering dust grains. Such ices are probed via mid-IR absorption spectroscopy, usually from satellite-based telescopes in order to avoid telluric absorption (Boogert et al. 2015). The major aim of interstellar ice spectroscopy experiments is to provide laboratory spectra of ices prepared under temperature and pressure conditions approaching those in space so that they can be used as a reference for the analysis of observational spectra.

A sample of molecules is prepared in the gas phase, then deposited onto a cold substrate (~ 10 – 20 K) inside an (ultra-)high vacuum chamber. The mid-IR absorption spectrum of the solid sample is measured in transmission using an IR spectrometer. The number of molecules deposited on the substrate is determined based upon the deposition rate (pressure) and time, allowing the spectrum to be converted into optical constants – i.e., the complex refractive index – via a Kramers-Kronig analysis (Hudgins et al. 1993). Finally, a spectrum on an optical depth scale is generated by application of corrections for scattering of light due to dust grains (Bohren and Huffman 1998) and of instrument-specific parameters such as spectral resolution. The resulting mid-IR spectrum can be compared to the observed ice

spectrum in order to identify the presence of specific molecules and to quantify their abundance along the observed line of sight (Boogert et al. 2015).

Many factors need to be taken into account when using laboratory spectra as references to benchmark observations, including physical parameters such as the deposition temperature, which influences the long range order of the deposited ice, the relative concentration of different ice components, which can modify the position, profile, and intensity of the vibrational modes of other molecules, and the structure of the ice – i.e., whether the molecules are deposited as a mixture or in layers – which also influences the optical properties of the solid.

A secondary aim of interstellar ice spectroscopy experiments is to understand the physical and chemical evolution of an ice by monitoring changes induced by different processes. An increase of the sample temperature can induce post-deposition diffusion of species on/in the ice, which may allow chemical reactivity to occur between molecules present in the ice, as well as modifying the ice structure. The introduction of energy into the ice in the form of irradiation by photons or bombardment with particles (ions, electrons, atoms, and molecules) may also modify the phase and/or composition of the ice. Using IR spectroscopy as a probe of the changes induced in the ice sample allows laboratory astrophysicists to extract quantities such as reaction rates, branching ratios, and activation energies for different chemical and physical processes. The integration of such data into solid phase or gas-grain astrophysical models is key in successfully simulating interstellar environments (Cuppen et al. 2017).

Interstellar ices are a reservoir for the generation of molecules of increasing complexity, both during the ice's formation and its subsequent processing. A current major focus of laboratory ice spectroscopy is the measurement of the spectra of predicted minor components of interstellar ices, such as complex organic molecules (COMs), in preparation for observations with the James Webb Space Telescope (JWST), which will have the sensitivity and spectral resolution to detect such molecules if they are present. Other developments include coupling solid phase vibrational IR

spectroscopy to other techniques, such as gas phase rotational millimeter/submillimeter spectroscopy, in order to monitor the exchange between the ice and the gas phases during processing of the ice (Yocum et al. 2019). In addition to the principal mid-IR spectroscopic range, other spectral regions may also be used for the study of ices relevant to specific astrophysical environments, for example, solid phase terahertz (far-IR/submillimeter) spectroscopy for the study of ices in protoplanetary disks (Min et al. 2016) and near-IR/visible spectroscopy for planetary and/or lunar ices in our own solar system (Gerakines et al. 2005).

Definition

Interstellar ices are volatile molecular solids that accumulate on the surfaces of cold interstellar dust grains. They are composed primarily of H₂O (typically 60–70% by number); other molecules observed or predicted to be present include CO, CO₂, CH₃OH, CH₄, NH₃, O₂, and N₂. Laboratory analog experiments reproducing space environments show that irradiation by photons, energetic particles, and thermal processing of these ice mixtures can lead to production of complex organic species, including amino acids. Interstellar ices

account for a major fraction of all the available CNO group elements in star-formation regions and are presumed to be primary carriers of these elements to protoplanetary disks, where they may become incorporated directly into icy planetesimals or may sublime, and undergo further chemical processing.

History

Ices were discussed as a probable ingredient of interstellar matter as early as 1935, soon after the presence of dust responsible for the extinction of starlight was confirmed (see Whittet 2003 for a review). It was first proposed by Lindblad (1935) that solid particles composed of H₂O, NH₃, and CH₄ could nucleate and grow in interstellar clouds; Jan Oort and Henk van de Hulst (1946) subsequently demonstrated that a realistic size distribution of such particles could account for the observed extinction. Subsequent models developed by Mayo Greenberg (1968) and others proposed that refractory dust particles composed of graphitic carbon or silicates provide nucleation sites for growth of ices in dense clouds, leading to the concept of core-mantle particles. The existence of interstellar ices was confirmed when observational facilities for infrared spectroscopy became available in the 1970s. It has long been suspected, following the development of the “dirty snowball” model for cometary composition in the early 1950s, that comets may inherit some presolar ices from the solar birth cloud, a still actively debated subject.

Overview

Interstellar ices are mainly detected and characterized by means of infrared absorption features that result from the vibrational motion of the molecules they contain and in few cases can be observed in emission in the far infrared implying ice network lower energy modes. Whereas gas-phase molecules produce infrared “bands” in which a vibrational energy level is split into multiple lines by rotation, a solid produces a

vibrational band for each vibrational mode because rotation is suppressed. Solid-state features are generally much broader than gas-phase lines, even at the low temperatures (10–100 K) appropriate to interstellar ices. Most of the important spectral features identified with the ices lie in the wavelength range 2–20 μm ; the most prominent of them is centered at 3 μm and arises from the O-H “stretching” mode of H_2O . An example of an infrared spectrum displaying interstellar ice features is shown below. The ices are observed against a continuum provided by a normal background field star (Elias 16, a K-type red giant) serendipitously located behind a cold core within a dense molecular cloud (Fig. 1).

Basic Methodology

Because an observed infrared feature is generally associated with the vibrational mode of a chemical bond rather than a specific molecule, identification is often ambiguous, especially for minor constituents. For example, all organic molecules containing C-H bonds are active in the 3.3–3.6 μm region of the spectrum, and the precise position, width, and shape of the feature produced by a given species depend on both the structure of the

molecule and the nature of the ice matrix in which it is embedded. The absorption profile also changes with the temperature and crystallinity of the ice. Laboratory data for interstellar analogues produced in laboratory experiments (see Fig. 2), simulating the space environment where reside dust grains covered by ice mantles in interstellar space and the different radiations at which are exposed these ice mantles, are therefore essential to aid interpretation of astronomical spectra.

Key Research Findings

Observations of the absorption features attributed to ice constrain the composition of the interstellar ice mantles and provide evidence of variations in both composition and structure with environment (e.g., Gibb et al. 2004; Dartois 2005; Boogert et al. 2015). In the cold, starless cores within interstellar clouds (i.e., regions that are yet to form stars), the ice is dominated by three species: H_2O , CO, and CO_2 . Of these, H_2O is always the most abundant (typically 60–70%). The ubiquity of H_2O requires that it must form in situ, primarily by reactions such as $\text{H} + \text{O} \rightarrow \text{OH}$ and $\text{H} + \text{OH} \rightarrow \text{H}_2\text{O}$ occurring on the surfaces of dust particles, because H_2O molecules formed by gas-phase

Interstellar Ices, Fig. 1 Composite infrared spectrum of Elias 16, a normal red giant star located behind a dense molecular cloud (a sketch of the observation configuration is shown on the right). Data from several instruments are included (the Short Wavelength Spectrometer of the

Infrared Space Observatory, the Infrared Spectrometer of the Spitzer Space Telescope, and ground-based telescopes). Spectral features of H_2O , CO, and CO_2 ices and of silicate dust are labeled. Note that narrow gas-phase lines are unresolved in this spectrum

Interstellar Ices, Fig. 2 Infrared spectrum of AFGL7009S, a massive young protostar located in a dense molecular cloud (right panel, lower trace, from the Short Wavelength Spectrometer of the Infrared Space Observatory). Above is shown a spectrum of a laboratory ice mixture analog, irradiated with ultraviolet photons, showing many spectral features of ices, that are labeled.

The contribution of the dust grains core (the silicates) not simulated in the laboratory is shown in brown. The ices present in the molecular cloud, probed by the protostar observation, are identified by comparing such laboratory analogue spectra to space observations (a sketch of the space observation configuration is shown on the left)

reactions are insufficiently abundant to account for the ice mantles by adsorption (freeze-out) onto the grains. CO is the only condensable gaseous interstellar molecule that is abundant enough to contribute significantly to the ices by direct adsorption. CO molecules sticking to a grain may be oxidized to CO_2 or may be hydrogenated first to HCO , H_2CO (formaldehyde), or CH_3OH (methanol) or chemically evolve in the ice mantle mixtures under the space radiation fields (ultraviolet photons, cosmic ray particles) to produce even more complex molecules. Ice mixtures dominated by H_2O are generally referred to as “polar” ices (i.e., they have a significant dipole moment). In regions of highest density within molecular clouds, ice-mantle growth proceeds also by direct freeze-out of gas-phase molecules, primarily CO. The CO-rich ice mixtures that form in such regions are generally referred to as “non-polar” ices (in reality they have a very small dipole moment). Observations of (e.g.,) the $4.67\ \mu\text{m}$ and $15.3\ \mu\text{m}$ infrared features of CO and CO_2 allow discrimination between the polar and nonpolar components, which display distinct absorption profiles.

Evolution of the ices in regions of active star formation is explored by observing ice features in the spectra of dust-embedded young stellar objects (i.e., protostars or pre-main-sequence stars in molecular clouds) and comparing them with those observed in background field stars that probe quiescent regions of molecular clouds (van Dishoeck and Blake 1998; Whittet 2003; Gibb et al. 2004; Oberg et al. 2011; Boogert et al. 2015). Protostars are typically luminous at infrared wavelengths, and the radiation they emit warms interstellar material in their local environs. Widespread evidence for heating of the ices is found: typically, the abundance of the relatively volatile nonpolar ice is reduced relative to the more robust polar ice due to sublimation; changes in profile shape are also observed and attributed to partial crystallization and segregation resulting from increased mobility of molecules in the ice matrix (e.g., Dartois et al. 1999; Pontoppidan et al. 2008; Poteet et al. 2013).

Heating may also drive chemical reactions by enabling activation energies to be overcome. Evidence for more dramatic changes driven by UV irradiation or particles accelerated to high energy

such as cosmic rays bombardment is also observed in the spectra of some luminous protostars, characterized by the appearance of a feature near 4.62 μm (Soifer et al. 1979; Lacy et al. 1984; Pendleton et al. 1999) attributed to synthesis of CN-bearing (cyanate) molecules in the ices (Bernstein et al. 1995; Elsila et al. 1997; Schutte and Greenberg 1997; Demyk et al. 1998; Hudson et al. 2001; Novozamsky et al. 2001; Raunier et al. 2003; Theule et al. 2011).

The gas-phase medium enriched by the desorbing or sublimating ices can be observed in dense clouds, in warmed interfaces close to nascent stars, in interstellar shocks on dense medium, using powerful radio telescopes (Cazaux et al. 2003; Bonfand et al. 2019; Manigand et al. 2021) and, for abundant ones, infrared observatories.

Future Directions

Interstellar volatiles are important to astrobiology because they represent a major reservoir of raw materials needed to form planets and life (Ehrenfreund and Charnley 2000; Herbst and van Dishoeck 2009). Important goals for future research will be to elucidate key astrochemical pathways toward complex molecule formation in the ices and their sublimates and to determine the extent to which the products survive disk accretion to become incorporated into icy planetesimals in protoplanetary disks. Progress toward solving the ice composition and abundance still unsolved problems requires a synthesis of research in observational astronomy (tighter observational constraints on abundances), laboratory astrophysics (measurement of rate constants and activation energies for key reactions, of energetic processing with photons, ions, thermal, shocks), and mathematical modeling. The development of robust models will allow the organic inventories of interstellar matter in prestellar cores and protoplanetary disks to be accurately constrained. The new-generation telescopes (ground- or space-based), probing protoplanetary disks in formation around other stellar systems, with a high angular resolution and allowing to constrain the composition of gas and ices as a function of the distance to the star

will advance the understanding of the interstellar heritage in disks. This will facilitate meaningful comparisons between interstellar matter and comets, which are accessible examples of icy planetesimals forming beyond the snowline in a protoplanetary disk. The composition study of solar system cosmomaterials (sample return missions, meteorites, interplanetary dust particles travelling in the solar system) that can be collected (with space probes or on Earth) and examined in detail in the laboratory, and which host the heritage of the realization of one particular (our solar system) among many protoplanetary disks of the Galaxy now observed with such generation telescopes with high angular resolution, is also one future direction.

ISM

Definition

The interstellar medium refers to the tenuous gas and dust that fills the void between stellar systems in galaxies. This gas and dust is not distributed uniformly in interstellar space but displays significant variations in density, temperature, and ionization state. The interstellar medium is held in place by the gravitational force of the stellar component of galaxies. The interstellar medium contains the raw materials out of which new stars are formed, and as stars die, material is returned to the interstellar medium, often violently, enriched by stellar nucleosynthesis. The cycling of material in and out of the interstellar medium plays a critical role in the evolution of galaxies.

Overview

The space between stellar systems in galaxies is called interstellar space, distinct from interplanetary space (the space within a stellar system) and intergalactic space (the space between galaxies). Interstellar space is not empty but is filled with rarefied gas and dust, and this gas and dust is what is commonly referred to as the interstellar medium. Besides gas and dust, interstellar space is also filled with ► [electromagnetic radiation](#) covering a vast range of wavelengths, energetic particles called cosmic rays, and magnetic fields, and these components have a strong influence on the physical properties of the interstellar gas and dust. The elemental composition of the interstellar medium is dominated by hydrogen, with lesser amounts of helium and only trace amounts of the elements heavier than helium. The most abundant of these trace elements, or what astronomers often refer to as the “heavy elements” or “metals,” are oxygen, carbon, and nitrogen. The state of the gas in the interstellar medium ranges from being a nearly fully ionized

plasma to being almost entirely in molecular form. The dust in the interstellar medium consists of small solid particles with a range of sizes, composed of both silicate and carbon grains (see ► [“Interstellar Dust”](#)). By mass, dust represents only about 1% of the interstellar medium; however, about half the mass of the heavy elements is in the form of dust.

The interstellar medium is best studied in the ► [Milky Way](#), where, as in other spiral galaxies, we find most of the gas and dust concentrated to the galactic midplane. The interstellar medium is held in place by the combined gravitational force of the stars in the Galaxy. The thickness of the gas and dust layer, often called the scale height, is determined by a balance between the forces of gravity and gas pressure (both thermal and turbulent), and in the Milky Way this layer is relatively thin compared with the dimensions of the Galaxy.

In the Milky Way, astronomers have identified a number of distinct “phases” of the interstellar medium. These phases of the interstellar medium are characterized by significant differences in the temperature, density, and ionization state of the gas. Six phases of the interstellar medium are recognized, which in decreasing temperature order are (1) the hot ionized medium (HIM), (2) ► [HII regions](#) (where the hydrogen is photoionized, H^+ regions), (3) the warm ionized medium (WIM), (4) the warm neutral medium (WNM), (5) the cold neutral medium (CNM), and (6) the molecular medium (MM). Table 1 summarizes the properties of the gas in each of these phases.

The dominant element, hydrogen, is found in ionized, neutral atomic, and molecular forms in the interstellar medium. The ultraviolet radiation in interstellar space can both dissociate hydrogen molecules and ionize atomic hydrogen. However, most hydrogen-ionizing radiation is localized near HII regions, so neutral atomic hydrogen is an important component of the interstellar medium. Some of the trace elements have ionization potentials smaller than hydrogen (13.6 eV [electron volts]) and can be ionized even in the neutral atomic hydrogen regions. Thus, elements such as carbon (ionization potential 11.3 eV) and iron

Interstellar Medium, Table 1 Properties^a of the gas in the different phases of the interstellar medium. Density is particle density and not mass density

Phase	Temperature (K)	Density (cm ⁻³)	State of hydrogen
Hot ionized medium (HIM)	10 ⁶	0.006	Ionized atomic
HII regions	10 ⁴	1–10 ⁴	Ionized atomic
Warm ionized medium (WIM)	8000	0.03	Ionized atomic
Warm neutral medium (WNM)	6000–8000	0.25	Neutral atomic
Cold neutral medium (CNM)	100	25	Neutral atomic
Molecular medium (MM)	10–20	10 ³ –10 ⁶	Neutral molecular

^aAdopted from Ferrière (2001) and Lequeux (2005)

(ionization potential 7.9 eV) are singly ionized in the CNM and WNM phases. In the densest regions, the molecular dissociating radiation cannot penetrate, and the rate of molecule formation is sufficiently rapid to form ► [molecular clouds](#) (the MM phase). The gas in each of these phases is roughly in thermal equilibrium, where the gas cooling rate per unit volume equals the gas heating rate per unit volume. However, the gas is not in thermodynamic equilibrium with the surrounding radiation field, dust, or cosmic rays. The dominant heating and cooling mechanisms for the gas are different for each of the phases. Since, in general, the cooling rates depend on the square of the gas density, while the heating rates depend linearly on gas density, the equilibrium temperature of the gas decreases with increasing gas density.

In the Milky Way, we have only a rough estimate of the volume occupied by the different phases and their contribution to the total mass of the interstellar medium. It is believed that by volume the interstellar medium is dominated by the lowest density phases (HIM, WIM, and WNM), while by mass, the interstellar medium is dominated by the highest density phases (MM, CNM, and WNM). In the inner regions of the Galaxy (within 8 kiloparsecs [kpc] of the Galactic Center), the mass is dominated by the molecular medium (MM), while in the outer regions of the Galaxy, the mass is dominated by the neutral atomic gas (CNM and WNM). The total mass of the interstellar medium in the Milky Way is uncertain but is estimated to be about 5×10^9 solar masses or about 5% of the stellar mass of the Milky Way (Lequeux 2005).

Basic Methodology

A variety of techniques are used to detect the gas and dust in the interstellar medium. The gas component is probed by observations of ► [spectral lines](#) that can be either in emission or in absorption against a background source of continuous radiation. The gas in the interstellar medium covers a vast temperature range. Since the wavelength or frequency at which emission lines from the gas in the interstellar medium are produced depends on temperature, observations extending from X-ray wavelengths to radio wavelengths are routinely used to probe the various gas phases. We summarize below some of the most common observations of the gas.

The earliest evidence for interstellar gas came from optical observations of bright nebulae. Spectroscopic observations of these bright nebulae by William Huggins in 1864 showed that the light was dominated by emission lines, indicating that these objects (which included both ► [HII regions](#) and ► [planetary nebulae](#)) were composed of diffuse hot gas. We now know that the gas in these bright nebulae is almost entirely ionized, and the prominent emission lines are the optical recombination lines of hydrogen and the forbidden lines of O⁺ (designated by astronomers as OII), O⁺⁺ (OIII), S⁺ (SII), and N⁺ (NII). The hydrogen recombination lines are produced when hydrogen ions recombine with an electron to form an excited electronic state, and this recombination is followed by a series of radiative transitions as the electron cascades down to the ground electronic state, producing an emission line spectrum. In addition, some ions have low-lying electronic

states (O^+ , O^{++} , S^+ , and N^+) that can be readily excited by collisions with electrons and, when they radiatively deexcite, produce observable emission lines at optical wavelengths. These emission lines are called “forbidden lines” since they are intrinsically weak magnetic dipole or electric quadrupole transitions and not the much stronger electric dipole transitions. The observed emission line ratios can be used to determine the density and temperature of the ionized gas in HII regions.

The neutral atomic hydrogen phases of the interstellar medium (WNM and CNM) are too cold for collisions of the gas to excite electronic transitions. The electrons in these atoms are consequently all in their ground electronic state. This neutral component was first detected in the early part of the twentieth century as the interstellar gas absorbed the light of background stars, producing interstellar optical absorption lines in stellar spectra. However, only a few atoms have resonance lines (absorption lines that arise from the ground electronic state) at optical wavelengths; instead most of these lines are in the ultraviolet, so these early observations were limited to only a few chemical elements. The launch of the Copernicus satellite in 1972 provided high-resolution ultraviolet [▶ spectroscopy](#) that permitted astronomers to study the most abundant elements (such as H, O, C, and N) in the mostly neutral atomic interstellar medium. Nevertheless, these absorption line observations are limited to the lines of sight toward relatively nearby bright stars.

The detection in 1951 of the emission from neutral atomic hydrogen at a wavelength of 21 cm provided a new avenue for studying the CNM and WNM phases of the interstellar medium. The ground electronic state of hydrogen is split into two very finely spaced sublevels due to the magnetic interaction between the spin of the proton and the electron. The energy splitting is extremely small, so the upper of the two hyperfine levels is readily excited by collisions even in the coldest phases of the interstellar medium. The subsequent magnetic dipole transition, although very weak, is detectable by radio telescopes. The 21-cm line was the first radio spectral line observed, and it provides the ability to detect

atomic hydrogen anywhere in the Galaxy. Emission from this transition is routinely used to map out the distribution of neutral atomic hydrogen in the Milky Way and other galaxies. The 21-cm line can also be seen in absorption against background radio sources. The combination of both emission and absorption observations allowed astronomers in the 1970s to determine the temperature of the hydrogen gas. These studies provided evidence that the neutral atomic gas in our Galaxy coexisted in both cold (100 K) high-density and warm (6000–8000 K) lower-density phases.

Besides the absorption lines expected to be present due the neutral atomic phase of the interstellar medium, the Copernicus satellite also detected absorption lines from a very highly ionized state of oxygen, O^{++++} (OVI). The high ionization potential of this ion (113 eV) excludes photoionization as an origin, leaving as the only possibility collisional ionization in a plasma with a temperature greater than 300,000 K. About the same time, a series of rocket flights (Wisconsin Survey) mapped the sky at X-ray wavelengths and detected diffuse soft X-ray emission from the interstellar medium. The soft X-ray emission is a combination of spectral line and bremsstrahlung (continuous) emission from a hot plasma. Both the ultraviolet absorption lines seen from high ionization species and the X-ray emission are evidence for a hot, low-density phase of the interstellar medium (HIM) reviewed in Spitzer (1990). Because the absorption line studies are limited to lines of sight toward relatively nearby bright stars and because the soft X-ray emission is readily absorbed by gas in the interstellar medium, we know little about the widespread distribution of the HIM in the Galaxy.

Prior to the detection of carbon monoxide (CO) emission via its pure rotational transition at 2.6 mm in 1970, molecular gas was thought to be only a very minor component of the interstellar medium. Absorption lines from a few simple molecules were detected at optical and ultraviolet wavelengths, suggesting that there was a small fraction of molecules in the neutral atomic phases. However, it was assumed that the ultraviolet radiation would effectively dissociate any molecule that formed. The detection of widespread CO

emission, however, changed this view and revealed a surprisingly new and important component of the interstellar medium that is largely molecular. The CO emission, although widespread, is associated with discrete molecular “clouds.” In these ► [molecular clouds](#), nearly all of the hydrogen is in molecular form. These unexpected large ► [dense clouds](#) can screen dissociating radiation from the cloud interior, allowing for molecules to form. Observations of the rotational lines of various molecular species permit the estimation of the density and temperature of these clouds. The molecular medium is the coldest and densest phase of the interstellar medium. Now well over 150 different molecular species have been detected in the molecular medium (MM) by their rotational transitions at centimeter, millimeter, and submillimeter wavelengths (see ► [“Molecules in Space”](#)).

The presence of free electrons in interstellar space produces a frequency-dependent delay in the pulsed radio signals from pulsars. The amount of time delay, called the pulsar dispersion measure, is directly related to the column density of electrons between the Earth and the pulsar. Observations in the 1970s of the pulsar dispersion measure provided evidence for a widespread distribution of free electrons in the interstellar medium (see review by Ferrière 2001). Later, the development of sensitive Fabry-Perot spectrometers permitted the detection of very extended but weak recombination line and forbidden line emissions at optical wavelengths (Reynolds 2004). These observations suggested the presence of a warm and ionized component of the interstellar medium (WIM). Prior to these observations, it was thought that photoionized gas was restricted to small isolated regions (called Strömgren spheres) surrounding luminous hot stars. However, these observations revealed that about 90% of the photoionized gas in the Milky Way is found in the more widespread WIM (Reynolds 2004).

Finally, the dust component of the interstellar medium can be detected either directly by its thermal emission at infrared wavelengths or by the effects of the intervening dust on the extinction and reddening of starlight. See entry on ► [Interstellar Dust](#).

Key Research Findings

Studies over the past century have revealed a complex multiphase interstellar medium in the Milky Way.

HII Regions

The oldest known component of the interstellar medium is HII (or H^+) regions. These are regions of ionized hydrogen gas surrounding luminous hot massive stars (O and B spectral type stars) which produce copious amounts of hydrogen-ionizing photons. The theory of HII regions dates back to Strömgren (1939), who showed that in ionization equilibrium (number of ionizations within a volume equal to the number of recombinations), the gas surrounding these hot stars will be nearly fully ionized out to a radius, now called the Strömgren radius, and is completely neutral beyond that radius. The size of HII regions depends on the density of the gas being photoionized and the rate at which the central star is producing hydrogen-ionizing photons. The gas in the HII region is heated by the photoionization process and cooled by the forbidden line emission and is typically around 8000 K. HII regions are not an important mass or volume component of the interstellar medium.

Two-Phase Interstellar Medium

The discovery of gas components (WIM, CNM) more pervasive than HII regions (see Methodology) gave rise to the first global theory of the interstellar medium. Field et al. (1969) examined gas in the interstellar medium in both thermal and pressure equilibrium. In their model the gas is heated by the energetic electrons produced by the cosmic-ray ionization of hydrogen. The gas is cooled through the collisional excitation of the fine-structure split levels of the ground electronic states of atoms and ions, such as C^+ and O, followed by a radiative transition that returns the atom or ion to its ground state. The emitted photon carries away kinetic energy, thus cooling the gas. Because the cooling rate has a strong dependence on both density and temperature, Field, Goldsmith, and Habing found that the neutral atomic hydrogen gas could coexist in two

stable phases in thermal and pressure equilibrium, one cold and dense (CNW) and a second warmer and less dense (WNM), in agreement with the combined hydrogen 21-cm emission and absorption observations. From this model developed the concept that the interstellar medium was composed of a “cloud” component (CNM) surrounded by an “intercloud” medium (WNM). Although the interstellar medium is much more complex than this early simple model, this concept is still useful for understanding the neutral atomic gas, and the model has been recently updated by Wolfire et al. (2003).

Three-Phase Interstellar Medium

The existence of a hot “intercloud” medium was first suggested by Spitzer (1956), who argued that such a medium was important for the pressure confinement of interstellar clouds. The UV absorption studies and X-ray observations, discussed earlier, revealed the presence of a very tenuous and hot component of the interstellar medium (HIM) as predicted by Spitzer. These hot interstellar bubbles are created by high-speed shocks produced by ► [supernova](#) blast waves that expand into the interstellar medium (Cox and Smith 1974). Because of the high temperature and low density of these supernova-created bubbles, Cox and Smith suggested that they would cool slowly and thus be relatively long lived. McKee and Ostriker (1977) produced one of the first models of the interstellar medium to incorporate the HIM, and in this model the structure of the interstellar medium was regulated by supernova explosions. McKee and Ostriker suggested that a multi-component interstellar medium resulted, in which a large fraction of the volume of the interstellar medium was filled with these hot bubbles. The fraction of the interstellar medium filled with the HIM has been a source of great debate; estimates as low as 10% to as high as 70% have been suggested. The volume fraction depends on both the frequency and clustering of supernovae and their subsequent evolution in the interstellar medium (Ferrière 2001; Cox 2005).

The model of McKee and Ostriker includes a diffuse ionized layer (WIM) to the WNM

component, ionized by diffuse stellar ultraviolet photons. However, the WIM is observed to be much more extensive than pictured in this early model. The WIM is estimated to occupy approximately 20% of the volume of the interstellar medium within 1 kpc of the galactic midplane (Reynolds 2004). Although the WIM is believed to be photoionized, why hydrogen-ionizing photons are so widespread is not yet well understood. In the traditional view, hydrogen-ionizing photons should all be contained within the Strömgren radius surrounding hot O and B stars in the Galaxy. However, if the hot bubbles produced by supernova explosions are pervasive and interconnected, then it may be possible for hydrogen-ionizing photons produced by hot stars to travel large distances, creating the observed widespread diffuse ionized component to the interstellar medium (Reynolds 2004).

Molecular Clouds

The molecular medium (MM) is the coldest and densest phase of the interstellar medium and, by definition, represents regions where the hydrogen is almost entirely in molecular form. This medium is sufficiently dense that the molecules that form by gas phase and grain surface chemical reactions are shielded against ► [photodissociation](#) by the interstellar ultraviolet radiation field. This gas can be probed by emission produced from excited rotational transitions of molecules that are excited by collisions. Since molecular hydrogen is a symmetric molecule, it does not have a permanent electric dipole moment and hence has only weak electric quadrupole transitions. In addition, molecular hydrogen is a light molecule (small moment of inertia), and therefore the rotational levels are widely spaced in energy, so even the lowest excited rotational levels of molecular hydrogen are rarely excited by collisions in these cold clouds. Therefore, the millimeter and submillimeter wavelength rotational transitions of heavier molecules with permanent dipole moments, such as CO (the next most abundant molecule after molecular hydrogen), are commonly used to measure the distribution of molecular gas in galaxies. Numerous surveys of CO emission have

been obtained that have mapped out the distribution of the molecular gas in the Milky Way (Combes 1991). The molecular and atomic gas components of the Galaxy have different distributions; the molecular gas is much more concentrated toward the center of the Galaxy than the atomic gas. Although the molecular component contains a significant fraction of the total mass of the interstellar medium within 8 kpc of the Galactic Center, it occupies a negligible fraction of the volume.

The molecular medium is made up of discreet units commonly referred to as “molecular clouds.” These molecular clouds are sufficiently dense that self-gravity is important. In fact, it is believed the molecular clouds are close to gravitational equilibrium, where the internal pressure of the molecular gas (which is dominated by macroscopic motions called turbulence and not microscopic thermal motions) is balanced by a combination of the cloud’s self-gravity and the pressure of the external medium. The molecular clouds are observed to be grouped together to form molecular cloud complexes. The masses of these molecular clouds and molecular cloud complexes range from 5 to 2×10^6 solar masses and have sizes that range from 0.2 to 80 pc (Goldsmith 1987). Most of the molecular mass resides in the most massive molecular clouds (Combes 1991). The clouds have a mean particle number density of approximately 1000 cm^{-3} , while the average density of cloud complexes is lower. In the nearest of these molecular clouds, dust mixed with the gas absorbs the light of background stars, and these clouds appear dark – the so called dark clouds (reviewed by Bergin and Taffalla 2007) (see entry on ► [Dust Cloud, Interstellar](#)). Within molecular clouds are denser regions called molecular cloud cores with densities of order 10^4 – 10^6 cm^{-3} , and it is in these cores that the gas is gravitationally collapsing to form new stars. The theory of star formation is complex and was recently reviewed by McKee and Ostriker (2007).

The molecular clouds are also of great interest because of their rich chemistry. Over 150 molecules have been identified in molecular clouds, many of them containing five or more atoms

(See entry on ► [“Molecules in Space”](#)). These complex organic molecular species are of particular relevance for astrobiology, as they may survive the formation of the Solar System and later be delivered to the early Earth by cometary and asteroidal impacts.

Summary

Astronomers believe they have identified all of the major phases of the gas and dust in the interstellar medium and have a reasonable estimate of the physical properties of each of these phases. The picture of the interstellar medium that has emerged is a multiphase interstellar medium in which cooler denser “clouds” (molecular clouds and the CNM) are embedded in a much warmer less dense “intercloud” medium (WNM, WIM, and HIM). The interstellar medium is very dynamic, as supernova explosions carve expanding hot bubbles in the interstellar medium that are relatively long lived. Many believe that supernovae play a dominant role in shaping the interstellar medium. In the atomic gas, both ordered and turbulence motions can produce over-dense regions (“clouds”) where self-gravity can begin to dominate. The densest regions of these clouds can collapse and form new stars (see entries on ► [“Hot Core”](#), ► [“Hot Corino”](#), ► [Star Formation, Observations](#)). Thus, the gas is constantly being cycled between phases of the interstellar medium and in and out of stars.

However, astronomers are far from having a complete understanding of this multiphase interstellar medium in the Milky Way, let alone in other galaxies. Observationally, we need a much better three-dimensional picture of how the various interstellar medium phases are distributed in interstellar space, particularly the CNM, WNM, and HIM phases. Although we know much about the detailed microscopic processes at work in the gas and dust, we lack a detailed theoretical model for the interactions of these phases and how the interstellar medium evolves with time, cycling between phases and ultimately forming stars. Much observational and theoretical work is needed to fully

understand the interstellar medium and the star formation process in galaxies.

Io

Therese Encrenaz
LESIA, Observatoire de Paris – Section de
Meudon, Meudon, France

Keywords

Galilean satellites

Definition

Io, discovered by ► [Galileo Galilei](#) in 1610 and named by Simon Marius (1614), is the Galilean satellite that is closest to ► [Jupiter](#). It orbits at a distance of 421,800 km (or about six Jovian radii) from the planet. With a diameter of 3640 km and a density of 3.5 g/cm³, Io is the densest Galilean satellite. This property is due to its proximity to Jupiter, which generates a strong internal energy due to tidal effects. As a result, in contrast with all other Galilean satellites, Io has lost all its water content.

Overview

Io's surface was revealed by the images of the ► [Voyager 1](#) spacecraft that flew over the satellite in March 1979 at a distance of only 20,500 km (or 11 satellite radii) and provided the first evidence for active volcanism outside the Earth. Io's surface shows no impact craters but several active volcanoes that replenish it on a short timescale. Fifteen years later, Io was explored again with the Galileo orbiter. From these observations, combined with the ► [HST](#) images, a temporal study of the volcanic evolution has been possible (Fig. 1).

The temperature of the active volcanoes can reach 1700 K, while the surrounding surface is at about 130 K. The main detected outgassed product is sulfur dioxide (SO₂), which freezes at the surface in white spots. Depending upon their temperatures, the sulfur compounds are black, red, or yellow. Silicate products are likely to be dominant

Io, Fig. 1 Io as observed by the Galileo spacecraft in 1995; note the volcanic plumes in the insets. (© NASA)

in the erupted magma, as indicated by the high temperature of the volcanoes. Their presence is consistent with models of Io's internal structure that predict a massive core of molten iron and (Fe, S) compounds, with a silicate mantle and crust.

The proximity of Jupiter induces a mechanical deformation due to tidal effects which would be stable in the absence of other satellites. However, due to gravitational perturbations linked to ► [Europa](#) and ► [Ganymede](#) (in resonance with Io), Io's deformation varies along its orbit, inducing a strong mechanical relaxation and heating, especially in the equatorial regions; this is where most of the volcanoes are found.

Io's volcanism produces a stable (although variable) atmosphere of gaseous SO₂ which was first identified in a plume by Voyager 1 in the infrared range and later confirmed from ground-based millimeter spectroscopy. The surface pressure ranges from 3 to 40 nanobars. SO and NaCl have been identified as minor atmospheric components by the same technique. Io's atmosphere is partially ionized by the ultraviolet solar radiation and by high-energy particles. This plasma is driven by the Jovian magnetic field to generate a torus around Jupiter at the distance of Io's orbit; indeed, Io's orbit crosses the Jovian magnetosphere. This torus was first detected through the ► [Ly \$\alpha\$](#) line by the Pioneer spacecraft. Further UV measurements led to the detection of S and O ions, and Na was detected

from visible ground-based observations. Io's torus was also studied in detail by the ► [Ulysses](#) spacecraft as it flew over the Jupiter system in 1992.

Ion-Exchange Chromatography

Mark Dörr
 University of Southern Denmark, Odense M,
 Denmark

Synonyms

[IEC](#)

Definition

Ion-exchange chromatography (IEC) is a laboratory separation process for the separation of ions and polar molecules based on their charge. It can be used for a multitude of charged molecules, including large molecules, such as proteins and oligonucleotides, and small molecules, such as amino acids. The stationary phase commonly consists of a resin or gel with a covalently linked charged molecule. Depending on the charge, IEC can be either anion- or cation-exchange chromatography. It is often used for protein purification, DNA/RNA oligomer analysis, and water analysis.

History

Ion-exchange chromatography is one of the oldest separation processes described in the literature. In 1850, H. Thompson and J. T. Way treated various clays (as a stationary phase) with ammonium sulfate or carbonate in solution to release calcium. During World War II, ion-exchange chromatography was further developed and played a crucial role in the “Manhattan project” to enrich radioactive elements.

[Ion-molecule reaction](#)

Definition

An ion-neutral reaction is a chemical reaction that occurs in a binary collision between one electrically charged species, an ion, and one electrically neutral species. As with ► [neutral-neutral reactions](#), the crucial properties that are sought in kinetic experiments are the *rate coefficient* and its dependence on temperature, denoted by $k(T)$ and, in cases where two or more sets of products are possible, the *branching ratio*, that is, the fractions of the overall reaction that proceed via different channels. For a bimolecular reaction, say $A^+ + B \rightarrow C^+ + D$, the rate of the loss of the ion A^+ , that is, $d[A^+]/dt$, is given by $-k(T) [A^+][B]$, where the square brackets denote concentrations,

The field editor A. Canosa informs that Prof. I. W. M. Smith has unfortunately passed away in 2016. Therefore, the field editor has included some complements along this contribution to maintain it as updated as possible

Ian W. M. Smith: deceased.

usually expressed in cm^{-3} , so that the units of $k(T)$ are $\text{cm}^3 \text{s}^{-1}$.

History

The occurrence of gas-phase ion-neutral reactions has been recognized since the development of mass spectrometry in the early years of the twentieth century. The ready occurrence of such reactions was shown by the detection of ions that could not be formed by the direct ionization of any neutral species that were known to be present. Indeed, such spurious signals could be viewed as a nuisance when the primary purpose of the experiments was to analyze the species present in a mixture of neutral species. Systematic studies of these reactions began in the early 1950s (Herman and Smith 1992). Most of the experimental work on ion-neutral reactions has been on the reactions of positively charged ions (*cations*), which are known to play a key role in the chemistry of the ► [interstellar medium](#). However, the recent discovery of negatively charged ions (► [anions](#)) in the interstellar medium is now stimulating laboratory work on the reactions of these species (Bierbaum 2011; Biennier et al. 2022).

Overview

The existence of an electric charge on an ion causes an attractive force between it and a neutral molecule, which is strong and acts over long range, compared with the interaction between two neutral molecules. This force arises between the charge on the ion and an electric dipole which it induces in the molecule and, if the molecule itself possesses a permanent electric dipole, between this dipole and the charge. The existence of these strong forces is frequently sufficient to cancel out any potential energy barrier resulting from rearrangement of the electrons as bonds make and break. Consequently, the rates of ion-neutral reactions are generally controlled by the rate at which the reactants “capture” one another and are brought into close contact by the attractive interaction.

When the neutral molecule does not possess a dipole moment, as is the case for H_2 , N_2 , CO_2 , and CH_4 , the strength of the attraction depends only on the distance apart of the two species, and a simple treatment, usually attributed to Langevin, leads to the prediction that the rate coefficient (using c.g.s-esu units) is given by $k(T) = 2\pi e (\alpha/\mu)^{1/2}$, where e is the electronic charge on the singly charged ion, α is the polarizability of the neutral charged molecule, and μ is the reduced mass, $m_A^+ m_B / (m_A^+ + m_B)$, of the colliding reactants. This formula is (a) easy to evaluate and (b) predict that the rate coefficient for ion-neutral reactions of this kind will not depend on the temperature. However, when the neutral molecule possesses an electric dipole moment, for example, in molecules like H_2O and NH_3 , the treatment of the capture process becomes more complicated, because the force between the reactants now depends not only on their separation but also on the orientation of the dipole with the line joining the centers of the two species. Several theoretical approaches have been adopted. They agree that the *average* attraction becomes stronger as the temperature is lowered and consequently $k(T)$ increases. Formulae fitting this effect have been proposed (Wakelam et al. 2010).

Figure 1 displays the temperature-dependent rate coefficients that have been measured for several ion-neutral reactions, comparing the results for two reactions between He^+ or N^+ ions and the nonpolar molecules N_2 and O_2 with those for two reactions of N^+ with the polar molecules H_2O and NH_3 . The rate coefficients for the first two reactions do not depend on temperature and are fairly close to the values predicted by the Langevin treatment, whereas the rate coefficients for the reactions of N^+ with H_2O and NH_3 increase as the temperature is reduced.

Basic Methodology

Experiments designed to obtain the rate coefficients (and branching ratios) of ion-neutral reactions fall into two main categories (Smith 2011). One is where combinations of electric and magnetic fields are employed to “trap” the ionic

Ion-Neutral Reaction, Fig. 1 Examples of rate coefficients for ion-neutral reactions, comparing results for reactions of ions with nonpolar and polar molecules with one another and with simple predictions. Experimental data for $\text{He}^+ + \text{N}_2$ (●) and $\text{N}^+ + \text{O}_2$ (●) are compared with the respective Langevin predictions, — and —. The rate coefficients for $\text{N}^+ + \text{H}_2\text{O}$ (●) and $\text{N}^+ + \text{NH}_3$ (●, ■) are compared with predictions based on expressions recommended by Wakelam et al. (2010), — and —. The experimental data for $\text{He}^+ + \text{N}_2$ and $\text{N}^+ + \text{O}_2$ are taken from Rowe et al. (1985), those for $\text{N}^+ + \text{H}_2\text{O}$ from Marquette et al. (1985), and those for $\text{N}^+ + \text{NH}_3$ (a) ■ from Marquette et al. (1985) and (b) ● from Rowe et al. (1995)

reactant and observe the rate of its loss by reaction when a neutral molecule is introduced to the reaction cell. In the second method, the ions are injected into a flowing gas, and the loss of the ion is observed when the neutral co-reactant is introduced to the gas flow. As both methods employ mass spectrometric detection, it is, at least in principle, possible to observe product ions and hence to obtain branching ratios.

The earliest form of the trapping methods used ion cyclotron resonance, where ions are constrained by a combination of electric and magnetic fields. After the introduction of the neutral co-reactant and after a selected time delay, the ions are transferred to an “analyzer region” where their (relative) concentration can be monitored (McMahon and Beauchamp 1972). Ion cyclotron resonance experiments were responsible for many of the rate coefficients that were used in early models of the interstellar medium (Prasad and Huntress 1980). Although this method has largely been employed to determine rate coefficients at room temperature, as explained above, the dependence of the rate coefficients for ion-

neutral reactions on temperature is frequently straightforward to predict. Trapping methods to determine rate coefficients at very low temperatures have been developed over a number of years by Dunn (1995), Gerlich (1995, 2008), and their coworkers. These experiments, especially those of Gerlich using a 22-pole trap, enable ions to be stored for minutes, thereby allowing the rate coefficients for very slow processes, such as the radiative association of C^+ with H_2 to form CH_2^+ at 10 K, to be measured.

The so-called flowing afterglow method was pioneered by Ferguson and his coworkers in the 1960s (Fehsenfeld et al. 1966; Dunkin et al. 1968). It is similar to the flow tube methods used to study the kinetics of neutral-neutral reactions, though the gas flows are greater and the gas dynamics must be carefully analyzed to extract rate coefficients. Ions are created at the upstream end of the flow tube, and changes in their concentration are monitored at the downstream end, as neutral reactants are added at one or more points along the flow tube.

There have been two major developments to the basic flowing afterglow technique. The first, originating with Adams and Smith (1976), was the introduction of a quadrupole mass filter between the ion source and the main flow tube. This makes it possible to select the reactant ion and the method is generally known by the acronym SIFT for selected ion flow tube. The second development, which allowed the first measurements of rate coefficients below ca. 90 K, was the invention of the CRESU (Cinétique de Réaction en Ecoulement Supersonique Uniforme or Reaction Kinetics in Uniform Supersonic Flows) technique by Rowe et al. (1984). Some details of this method are given in the entry on “► Neutral-Neutral Reaction.” In the study of ion-neutral reactions, ions were generated by irradiation with an electron beam that crossed the supersonic flow of gas just downstream from the exit of the Laval nozzle. Although the CRESU method has been applied to a limited number of ion-neutral reactions, the results have been invaluable in demonstrating how the temperature dependence of the rate coefficients differs when ions react with nonpolar and polar molecules (see Fig. 1).

Key Research Findings

Measurements of the rate coefficients for a large number of ion-molecule reactions (Anicich 1993a, b) by the methods described in the previous section have confirmed that, for the majority (but not all) of exothermic reactions, the observed rate coefficients are close to those suggested by the simple capture theories and that the rate coefficients remain approximately the same or increase as the temperature is lowered. The rate coefficients may be lower than the simple predictions in those cases where both the ion and neutral species have unpaired electrons, since then reaction can only occur in the fraction of collisions in which electrons – one from each species – pair up to form a chemical bond.

Applications

Ion-molecule reactions play an important role in the chemistry of the upper levels of the Earth's atmosphere. However, and especially in the context of this encyclopedia, the principal application of the rate coefficients for ion-molecule reactions is in the modeling of the ► [interstellar medium](#), especially the cold (ca. 10 K) cores of dense, dark interstellar clouds, where H_2 is the dominant species present and where many of the known interstellar molecules have been detected.

The chemistry in these regions of the cosmos, which serve as the birthplace of stars, is initiated by the ionization of molecular hydrogen, H_2 , followed by the reaction of the H_2^+ ions that are formed with the relatively abundant H_2 molecules to form H_3^+ :

The proton affinity of H_2 is not very high so the ion H_3^+ can undergo facile ion-molecule reactions in which a proton is transferred from it to a neutral reactant. This occurs with O atoms, C atoms, and N_2 , creating OH^+ , CH^+ , and N_2H^+ and initiating networks of (largely) ion-molecule reactions that

lead, inter alia, to molecules such as H_2O , CH_4 , and NH_3 .

It is worth mentioning that ion-molecule reactions found a practical outlet in analytical technologies since they chemically generate ion products that are identifiers of the neutral partner B. Devices like the selective ion flow tube–mass spectrometer (SIFT-MS) or the proton transfer–mass spectrometer (PTR-MS) and their various derivatives are based on the knowledge of rate coefficients and branching ratios of ion-molecule reactions at room temperature involving either H_3O^+ , NO^+ , or O_2^+ . These tools are presently widely used to identify and quantify trace concentrations of volatile organic compounds (Spanel et al. 2019) in the air outdoors or indoors.

Future Directions

Recent modeling calculations (Wakelam et al. 2010), which identify the reactions that are key in determining the abundances of the major molecular species observed in ► [dense interstellar clouds](#), have shown that reactions of ions with radical atoms are especially important. Such reactions have been studied recently at room temperature in SIFT experiments in which flow-discharge techniques (see section on “► [Neutral-Neutral Reaction](#)”) are used to generate measured concentrations of atoms. The results of these experiments – on reactions of both positive and negative ions – have been reviewed by Snow and Bierbaum (2008). The rate coefficients of such reactions may be lowered if the ion as well as the radical atom has unpaired electrons. Furthermore, although radical atoms cannot possess an electric dipole moment, additional attraction to an ion can arise if the electrons in the atom are not symmetrically distributed around its nucleus, and this can lead to an acceleration in the rate of reaction with an ion as the temperature is lowered. This effect is predicted for the important reaction of O atoms with H_3^+ ions (Bettens et al. 1999; Klippenstein et al. 2010). Experimental confirmation of these predictions is desirable.

Determination of branching ratios (see section “[Definition](#)” above) is also of fundamental

importance for chemical networks trying to mimic the interstellar medium chemistry. Although there is now a great deal of data at room temperature, the temperature dependence of branching ratios is generally unknown and data below 200 K are essentially nonexistent (Biennier et al. 2022). It is often assumed that branching ratios do not depend on temperature but this needs to be verified either experimentally or theoretically. As a matter of example, the reaction of He^+ with methyl formate (HCOOCH_3) is expected to form only $\text{HOCO}^+ + \text{CH}_3$ in astrochemical networks. However, recent experimental investigations (Ascenzi et al. 2019) at high temperature revealed that the $\text{HCO}^+ + \text{CH}_3\text{O}$ route was largely dominant (83%) and other minor channels were also identified forming CH_3^+ (7%), OCH_3^+ (4%), or CH_2^+ (4%) whereas HOCO^+ was totally negligible (<1%). Will the branching ratios be identical at the very low temperatures of dense interstellar clouds? Further laboratory investigations are clearly desirable for this system and many others.

Ionization Constant

Henderson James Jim CleavesII

Washington, DC, USA

Definition

An ionization constant refers to the degree that an ionic bond is dissociated in solution. This can describe many important chemical phenomena, including acid and base dissociation and water self-ionization. The self-ionization of water occurs when two water molecules disproportionate to yield a hydronium (H_3O^+) ion and a hydroxide (OH^-) ion:

The occurrence of this reaction is evidenced by the electrical conductivity of pure water. The ionization of water actually occurs in two steps. First, the electronegative oxygen atom in water abstracts the electron from an attached hydrogen atom, yielding a proton which may dissociate:

The resulting hydrogen ion (or proton, H^+) may then react with another water molecule to form the hydronium ion:

In pure water at 25°C, the concentration of H_3O^+ or OH^- ions at equilibrium is 10^{-7} M. The equilibrium between the ions and the water molecules can be used to define the ionization constant of water:

The concentration of each molecule is expressed in terms of molarity. Substituting the values of 10^{-7} M given above and the molarity of water ($1000 \text{ g L}^{-1} * 1/18 \text{ moles g}^{-1} = 55.5 \text{ M}$) gives an equilibrium constant (the ionization constant) of $1.8 * 10^{-16}$ M. But since the concentration of water is generally nearly constant in most contexts (depending on temperature and ionic strength, though, among other factors), the expression below is typically used:

$$K_w = [\text{H}_3\text{O}^+][\text{OH}^-] = 10^{-14}$$

Acid and base behavior can also be described in terms of ionization constants. Acid dissociation constants, which are a specific type of ionization constant, describe the extent to which an acid dissociates, for example:

At equilibrium, the rates of the forward and back reactions are equivalent, and the concentrations of the products and reactants are essentially constant. Their equilibrium relationship (the acid dissociation constant K_a) can then be expressed:

$$K_a = [\text{H}_3\text{O}^+][\text{CN}^-]/\text{HCN}$$

Similar calculations can be carried out for any compound which tends to dissociate to give ionic species in solution, including salts and metal-ligand complexes.

Synonyms

[Biological radiation effects](#)

Definition

Radiation interacts with matter primarily through ionization and excitation of electrons in atoms and molecules. There are two alternative ways of radiation damage to biological key substances: either by direct energy absorption (direct radiation effect) or via interactions with radicals, for example, those produced by radiolysis of cellular water molecules (indirect radiation effect). For direct radiation effect, the mean number of injured molecules, for example, DNA, is directly proportional to the dose. For indirect effects, the number of changed molecules increases with increasing ► [linear energy transfer \(LET\)](#). ► [Mutations](#), cancer induction, and cell death are the most critical biological radiation effects.

Definition

IRAS 16293-2422 is a low-mass ► [protostar](#) located at a distance of 141 (+30, −21) pc (Dzib et al. 2018) in the L1689 cloud, which is part of the Rho Ophiuchi ► [molecular cloud](#) complex. This binary source is formed of the components IRAS 16293A and IRAS 16293B, which are separated by 5.1 arcsec (i.e., 719 AU at 141 pc). This deeply embedded object belongs to the Class 0 stage (André et al. 1993) and is well-known for its richness in ► [complex organic molecules](#) as well as its high ► [deuterium](#) fractionation.

History

This source detected in the 1980s with the ► [Infrared Astronomical Satellite](#) was quickly known for its rich molecular line spectrum (e.g., van Dishoeck et al. 1995). The interest for this protostar strongly increased with the detection of a wide variety of ► [complex organic molecules](#) characteristic of hot molecular cores (e.g., CH₃CHO, CH₃OCHO, CH₃OCH₃, and C₂H₅CN) by Cazaux et al. (2003). It was the first time that such molecules were found in a low-mass ► [protostar](#). To better characterize its molecular content, several large spectral surveys were subsequently observed towards this source:

- The IRAS 16293-2422 millimeter and submillimeter spectral survey (TIMASSS, Caux et al. 2011) at 3, 2, 1, and 0.9 mm with the IRAM 30 m and JCMT single-dish telescopes
- The Chemical HERSchel spectral survey (CHESS, Ceccarelli et al. 2010) with the HIFI instrument on board the ► [Herschel](#) Space Observatory between 480 GHz and 1.9 THz
- A high angular resolution survey of several bands in the 215.6–231.4 GHz and 336.8–353.1 GHz ranges with the Submillimeter Array (Jørgensen et al. 2011).
- The Protostellar Interferometric Line Survey (PILS, Jørgensen et al. 2016) with the Atacama Large Millimeter/submillimeter Array (► [ALMA](#)) between 329 and 363 GHz

These different ► [molecular line surveys](#) led to the most complete molecular census in a Class 0 protostar, which makes IRAS 16293-2422 an astrochemical template for this type of sources.

Overview

Physical Structure

IRAS 16293-2422 breaks up into two protostellar components, IRAS 16293A and IRAS 16293B. A dust filament connects the two protostars

(Pineda et al. 2012; Jørgensen et al. 2016). According to a 3D modelling of the source (Jacobsen et al. 2018), IRAS 16293A (18 solar luminosities) would be more luminous than IRAS 16293B (3 solar luminosities). Some previous high angular resolution observations suggested that IRAS 16293A could be a binary itself with its two components separated by about 1'' (e.g., Chandler et al. 2005). It was, however, not confirmed with recent ALMA observations of the source (Jørgensen et al. 2016). This would, consequently, rather support the presence of a relatively edge-on disk, as suggested by a velocity gradient observed in the North East-South West direction (e.g., Pineda et al. 2012). The lines observed with ALMA towards IRAS 16293B show inverse P-Cygni profiles, which indicates that the gas is infalling in the inner regions of this component. An East-West bipolar outflow and a North West-South East outflow are seen around IRAS 16293A, while no obvious outflow seems to come from IRAS 16293B (Yeh et al. 2008; Kristensen et al. 2013).

Chemistry

Thanks to the numerous spectral surveys carried out towards IRAS 16293-2422, it was found that this low-mass source is as chemically rich as massive hot cores. Most of the first detections of ► [complex organic molecules](#) in solar-type protostars were obtained towards IRAS16293-2422. Some of the detected molecules present a prebiotic interest: for example, the simplest sugar-type molecule, ► [glycolaldehyde](#) (CH₂OHCHO, Jørgensen et al. 2012), the molecules with a peptide-like bond, ► [formamide](#) (NH₂CHO, Kahane et al. 2013) and methyl isocyanate (CH₃NCO, Ligerink et al. 2017; Martin-Domenech et al. 2017), and ► [cyanamide](#) (NH₂CN, Coutens et al. 2018). IRAS 16293-2422 is also famous for its first interstellar detections of ► [chloromethane](#) (CH₃Cl, Fayolle et al. 2017) as well as many deuterated ► [complex organic molecules](#) (Coutens et al. 2016; Jørgensen et al. 2016).

IRC+10216

Hans Olofsson

Department of Earth and Space Sciences,
Chalmers University of Technology, Gothenburg,
Sweden

Definition

IRC + 10216, also known by its variable star name CW Leonis, is a ► [red giant](#) star on the asymptotic giant branch with a carbon-rich atmospheric composition, i.e., the atmospheric abundance of carbon exceeds that of oxygen. It is probably the most nearby object of its kind, and it loses substantial amounts of matter from its surface. This stellar wind creates a dense circumstellar envelope which is rich in molecules and carbon dust. More than 80 different circumstellar molecular species have been detected, the majority being long, unsaturated, carbon chains of different types (incl. anions) and many of them being unique to the circumstellar medium.

Iridium

Philippe Claeys

Analytical-Environmental & Geo-Chemistry,
Vrije Universiteit Brussel, Brussels, Belgium

Definition

Iridium is a hard, brittle, corrosion-resistant metal with the symbol $_{77}\text{Ir}$. It is one of the platinum group elements (or PGE) – ruthenium, rhodium, palladium, rhenium, osmium, iridium, and platinum – which are highly siderophilic and form

strong bonds with iron. Most of the terrestrial PGE are concentrated in the core, leaving the mantle and crust highly depleted in Ir (ca. 3 and < 0.05 ppb, respectively). In comparison, undifferentiated meteorites (meteorites that have not suffered geological evolution) are enriched in PGE (ca. 200–500 ppb). Elevated PGE concentrations measured in terrestrial rocks can indicate a meteoritic contribution. The detection of the iridium enrichment in the KT Or K-Pg boundary clay layer first found in Gubbio, Italy, and then confirmed all over the world, led to the meteoritic impact hypothesis as a possible cause of the dinosaur extinction. The determination of PGE elemental ratios in impactites can contribute to the identification of the type of impacted meteorite.

Iron

Ricardo Amils

Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Definition

Iron is a transition element with three natural states of oxidation Fe^0 (metal), Fe^{2+} , and Fe^{3+} . It is abundant in planetary material, mostly as Fe^0 and Fe^{2+} . In the Earth, most iron resides in the metallic core and in the mantle where it forms abundant minerals, with Mg. Under hydrous conditions, Fe^{2+} is highly soluble, whereas Fe^{3+} is

highly insoluble and precipitates as iron (oxi)-hydroxy. In contact with the atmosphere ($\text{H}_2\text{O}-\text{O}_2$) the stable form of iron is Fe^{3+} . Iron sulfides (e.g., ► [pyrite](#)) are highly insoluble. Iron is a fundamental element for life. Iron plays a major role in critical cellular functions like ► [respiration](#), nitrogen fixation, or oxygen detoxification. Under anoxic conditions, iron is generally in its reduced state (ferrous iron, Fe^{2+}) and soluble. In aerobic conditions, iron is generally oxidized (ferric iron, Fe^{3+}) forming different insoluble minerals. At neutral pH, iron is insoluble and non-bioavailable. Consequently, organisms produce iron-binding agents called siderophores that efficiently bind iron and transport it into the cell. Iron is a good ► [electron donor](#), so it can be used as a source of energy, and also is an ► [electron acceptor](#), thus can be used for ► [anaerobic respiration](#). Iron-oxidizing and iron-reducing microorganisms are the base of the biogeochemical cycle of this element. Ferric iron is also a good buffer, controlling the pH at acidic conditions and a protective agent against UV radiation, a property of astrobiological interest. The UV irradiation of ferrous iron, the Fenton reaction, produces very reactive radicals that can damage functional sites of proteins and nucleic acids. Iron is stored in ferritin particles in its oxidized, less reactive form, to protect cells. This protective mechanism is ancestral and universal. Ferritins are found in most organisms from the three domains. Some prokaryotes can grow in the absence of iron like *Lactobacillus plantarum* or *Borrelia burgdorferi*. In these bacteria, Mn^{2+} substitutes for iron as the metal component of enzymes that normally contain Fe^{2+} .

Definition

The ► [iron](#) cycle is the biogeochemical cycle that couples the oxidation and reduction reactions of iron, a key element for life.

Overview

Iron is one of the most abundant elements in the universe. On the Earth's surface and in its crust, iron exists in two oxidation states, ferrous (Fe^{2+}) and ferric (Fe^{3+}) iron. Fe^0 does not exist in nature; it is a major product of industrial activity generated by smelting iron minerals to produce cast iron. The oxidation of ferrous iron can be produced both chemically and biologically through chemolithotrophy. The reduction of ferric iron occurs geochemically and in ► [anaerobic respiration](#), as the result of its use as an ► [electron acceptor](#). Ferric iron precipitates at neutral and alkaline pH as ferric hydroxide.

Iron Oxidation

At neutral pH, ferrous iron is oxidized rapidly in the presence of oxygen. Several prokaryotic microorganisms can obtain energy by oxidizing reduced ferrous iron. In neutral habitats, Fe^{2+} can

be oxidized by iron bacteria such as *Gallionella* and *Leptothrix*. In this case, these microorganisms require mechanisms that can compete efficiently with the rapid chemical oxidation produced by oxygen. These microorganisms grow mainly at interfaces between ferrous-rich anoxic groundwaters and air. However, the most extensive microbial iron oxidation occurs at acidic pH, where Fe^{2+} is stable and not subject to spontaneous oxidation. In extremely acidic habitats, the acidophilic chemolithotrophic *Acidithiobacillus ferrooxidans* and *Leptospirillum ferrooxidans* oxidize Fe^{2+} to Fe^{3+} . Very little energy is produced in this reaction; thus these microorganisms must oxidize large amounts of iron to generate enough energy to grow. *A. ferrooxidans* and *L. ferrooxidans* are phylogenetically, morphologically, and metabolically very distinct. While *L. ferrooxidans* can grow only on Fe^{2+} , *A. ferrooxidans* grows chemolithotrophically on either ferrous iron or reduced sulfur compounds, such as elemental sulfur (S^0).

One of the most common forms of iron in nature is ► [pyrite](#). Bacterial oxidation of pyrite is of great environmental (generation of acid mine drainage) and biotechnological (biomining) importance. The mechanisms by which acidophilic chemolithotrophs can obtain energy from mineral sulfides have been a source of controversy for many years. But the demonstration that the ferric iron present in the cell wall and the extracellular polysaccharides of these microorganisms are responsible for the electronic transfer from the insoluble mineral substrate (pyrite) to the electron transport chain has clarified this issue, with important fundamental and applied consequences. As we will see, the oxidation of sulfides is a combination of chemically and microbially catalyzed reactions. The differences observed during the bioleaching of diverse metallic sulfides are a consequence of the chemical attack mechanisms, which depend on the crystallographic structure of the mineral substrates. In nature, three sulfides, pyrite, molybdenite, and tungstenite, can be oxidized by ferric iron through the so-called thiosulfate mechanism shown in Eqs. 1 and 2:

The sulfuric acid produced in these reactions requires only the oxidative action of ferric iron. The rest of the sulfides (sphalerite, galena, chalcopyrite, etc.) undergo oxidation through the polysulfide mechanism (Eqs. 3 and 4):

In this case, there is no direct production of sulfate. The elemental sulfur can be further oxidized by sulfur-oxidizing microorganisms generating sulfuric acid according to Eq. 5:

The critical role of iron-oxidizing microorganisms, such as *L. ferrooxidans* and *A. ferrooxidans*, in the bioleaching of metal sulfides is to maintain a high concentration of the oxidizing agent, ferric iron (Eq. 6):

Furthermore, it is now well established that iron can be oxidized anaerobically in the absence of oxygen using nitrate (and probably other compounds) as an electron acceptor (Eq. 7):

In addition, the hydrolysis of ferric iron further releases protons, a buffer reaction that is responsible for the constant pH observed in these systems (Eq. 8):

These reactions explain most of the properties observed in different extreme acidic environments, which are under the control of iron (Fig. 1).

Iron Reduction

Many microorganisms can use ferric iron as an electron acceptor (e.g., *A. ferrooxidans*, *Acidiphilium* spp., or *Geobacter metallireducens*, which in anoxic conditions can obtain energy respiring anaerobically). Ferric iron reduction is

common in anoxic environments such as lake sediments and bioleaching heaps. Movement of iron-rich groundwater from anoxic waterlogged soils can result in the transport of large amounts of ferrous iron. When this iron-laden water reaches oxic environments, ferrous iron is oxidized chemically or by iron-oxidizing microorganisms, precipitating ferric compounds. Ferric hydroxide precipitates can interact with reduced organic compounds, like humic acids, to reduce ferric iron back to ferrous iron. Ferric iron can also form complexes with different organic compounds. In this way, iron becomes solubilized and once again available to ferric-reducing microorganisms as an electron acceptor.

In Fig. 1, a display of the iron cycle operating in the Río Tinto basin coupled to a sulfur cycle is shown. Due to their characteristics, the iron and sulfur cycles are considered important model systems of astrobiological interest.

Iron Cycle, Fig. 1 Geomicrobiology of the Río Tinto basin, a geochemical terrestrial analog of Mars, showing the microbial activities associated with the operation of the iron and sulfur cycles

Definition

Iron has four naturally occurring stable isotopes: ^{54}Fe , ^{56}Fe , ^{57}Fe , and ^{58}Fe of respective abundances 5.80%, 91.72%, 2.20%, and 0.28%. They are increasingly used to determine the source of the iron present in geological or biological materials and/or to characterize the chemical reactions that may have led to the form of iron under study. The isotopic signature of Fe is particularly sensitive to redox effects, including certain biological reactions such as bacterial dissimilatory iron reduction (DIR).

Overview

Although less variable in abundances than carbon or oxygen stable isotopes, iron isotopes show analytically significant mass-dependent isotopic variations in nature. The geochemical community has investigated the range of Fe isotope compositions in both high- and low-temperature geological environments. Contrary to early expectations, there are no specific biological-type iron isotope signatures. On the other hand, the largest isotopic fractionation was observed for low-temperature redox reactions, and biological dissimilatory iron reduction (DIR) is one of those biological reactions that affect significantly iron isotope compositions. Another requirement for inorganic or organic reactions to leave an isotopic imprint is that the reaction exchange is not complete, that is, not all of the original pool of iron has been consumed. Nature-based and experimentally based astrobiology studies have shown that iron isotopes are particularly useful to study traces of life and/or their environment when used in conjunction with other mineralogical, biological, and chemical indicators.

Basic Methodology

The isotopic composition of iron in natural samples has been measured since the 1940s by electron impact ionization and, more recently, by thermal ionization mass spectrometry (TIMS) after sample dissolution and chemical purification

using anion exchange chromatography. The level of precision reached relative to natural variations rendered the study of Fe isotope signatures of little interest until the end of the twentieth century. The advent of the second generation of multiple collector inductively coupled plasma mass spectrometers (MC-ICP-MS) led to an order of magnitude improvement in analytical precision (Belshaw et al. 2000). This opened the way to an exponential development of these “non-traditional isotopes,” such as iron isotopes. Although the purification chemistry is straightforward and has been known for some time (Strelow 1980), MC-ICP-MS techniques vary among laboratories. Mass bias corrections range from the simple sample-standard-bracketing approach to more sophisticated Cu- or Ni-doping methods. A few groups have also adopted the double spike technique, which remains the only way to determine precise Fe isotope composition by TIMS. Isotopic results are conventionally reported using the delta notation with reference to the IRMM 14 reference material (unfortunately no longer available from the European Institute for Reference Materials and Measurements, Geel, Belgium, but it may be conveniently replaced by the IRMM 524A reference material) that has a composition close to that of chondrites. For example,

$$\delta^{57}\text{Fe} (\text{‰}) = \left(\frac{{}^{57}\text{Fe}/{}^{54}\text{Fe}_{\text{sample}}}{{}^{57}\text{Fe}/{}^{54}\text{Fe}_{\text{IRMM14}}} - 1 \right) \times 10^3$$

and this notation can be equally defined for $\delta^{56}\text{Fe}$. Some groups still report their Fe isotope compositions with reference to average of igneous rocks. Although being isotopically homogeneous, this convention should be abandoned since some igneous rocks depart significantly from this average value (e.g., some granites from the Earth's continental crust; Poitrasson and Freydier 2005), and therefore, this may generate some confusion among nonspecialists.

Key Research Findings

A first important finding is that the iron isotope compositions of igneous rocks that form the

Earth's crust vary very little. As a result, they make a baseline against which low-temperature, superficial biogeochemical processes that display larger isotope variations may be compared to (Beard et al. 2003; Poitrasson 2006). Various field-based, experimental, and especially theoretical studies conducted over the past two decades revealed that the main driving factors generating Fe isotope variations are redox and coordination chemistry changes. For example, the largest equilibrium Fe isotope fractionation among two coexisting iron reservoirs ($\sim 4.5\text{‰}$ in $\delta^{57}\text{Fe}$) was observed between aqueous Fe^{2+} and Fe^{3+} species (Welch et al. 2003; Anbar et al. 2005). The importance of the bonding environment on Fe isotope signatures is best illustrated by theoretical prediction of Fe isotope fractionation between mineral phases holding iron in the same redox state, but with different network-forming anions, such as in sulfide and carbonate minerals (Polyakov and Mineev 2000; Blanchard et al. 2009). Ab initio computations also illustrate the importance of iron coordination chemistry and nature of aqueous ligands to interpret the Fe isotope composition of environmental samples (Fujii et al., 2014). The finding that mass-dependent Fe isotope variation occurs in nature is interesting in itself. Even more important however is the discovery that for the same rocks, the stable isotopes of iron show contrasted fractionation when compared to those of carbon (Matthews et al. 2004). Although not unexpected given the contrasted interatomic bonding environments of Fe and C, this illustrates that the stable isotopes of different elements can trace different processes and/or different properties of the studied reservoirs. As such, combining different isotopic tracers is certainly a promising approach for future research, notably to detect biological activity (Johnson et al. 2008; Severmann and Anbar 2009).

Applications

Since astrobiology aims at looking for traces of life on the early Earth and on planets other than the Earth, one would ideally do precise Fe isotope measurements of extraterrestrial samples to

determine signatures that could be tracking life or at least environmental conditions suitable for life. However, the need for high-precision mass spectrometry methods that were established in terrestrial laboratories over the past decade makes such delicate measurements on robotic missions on other planets impossible at present. Aside for the Moon that has never been prone to the development of life since the beginning of its history given its extreme temperatures, lack of liquid water, and lack of atmosphere, we should wait for sample return missions from other planetary bodies. In the meantime, we have to rely on meteorites thought to come from planets where life may have existed, such as Mars. However, Martian meteorites that belong to the Shergotty, Nakhla, and Chassigny (SNC) class are essentially igneous rocks. Hence, looking for traces of life on those rocks using iron isotopes was unsuccessful (Anand et al. 2006). This was not unexpected given that even if traces of life were searched on bulk terrestrial fresh igneous rocks, the igneous rock Fe isotope signature would have likely overwhelmed the biologically processed Fe. Another limitation is that despite initial expectation (Beard and Johnson 1999), there are, like for carbon isotopes, no unique Fe isotope biological signatures (Anbar et al. 2000). Indeed, inorganic processes may also produce strong Fe isotope fractionation leading to light products, notably when kinetic effects are involved. Hence, the use of Fe isotopes to search for traces of biological activity should necessarily be conducted in conjunction with other mineralogical, chemical, and isotopic indicators.

Astrobiology also looks at extreme terrestrial environments where life may occur despite hostile conditions. This is the case of acid mine drainage waters from the ► [Rio-Tinto-Odiel](#) sulfide deposit basin, southern Spain, that is characterized by anomalously acidic waters ($1.5 < \text{pH} < 3.9$) containing elevated concentrations of dissolved Fe ($>20,000$ ppm). Despite these conditions, bacterial activity occurs. This geological setting is of interest to astrobiologists because it forms specific minerals including ► [jarosite](#) that also occur at the Martian

Meridiani Planum site. Iron isotopes were used by Egal et al. (2008) to study this Spanish site. Although the biological activity imprint could not be detected through Fe isotope compositions, this study combined mineralogical, aqueous geochemistry, and iron isotope determinations to put constraints on the mechanisms that led to the formation of such an extreme geochemical environment on Earth.

Archean ► [apex cherts](#) from Marble Bar, Western Australia, is another interesting geological case study for astrobiologists since it has been claimed to contain the oldest fossils of microbes found yet on Earth, ca. 3.5 Ga years ago, although this finding generated a lot of debate. Pinti et al. (2007) used iron isotopes to study Fe-Mn-oxyhydroxides containing C and N with a biological-like isotopic signature that occur in these cherts. They found $\delta^{57}\text{Fe}$ values compatible with oceanic hydrothermal precipitation, thereby strengthening the inference that C and N isotope compositions mark 3.5 Ga old biological activity.

Archean banded iron formations (BIFs) are also obvious geological records to look for ancient traces of life. Combining a detailed petrographic study with C, O, and Fe isotope investigations of carbonates from these sedimentary formations led Heimann et al. (2010) to highlight the importance of bacterial dissimilatory iron reduction back to ca. 2.5 Ga ago. Studying again Fe and C isotopes in magnetites and carbonates from BIFs of ca. 2.5 and 3.8 Ga, Craddock and Dauphas (2011) concluded that this bacterial process is in fact recorded in the oldest available sedimentary rocks we have on Earth.

Experimental investigations may also help to study processes that may have occurred on the early Earth. For example, Gronstal et al. (2009) examined experimentally how the first living organisms on Earth, that is, prokaryotes, could have extracted energy by oxidizing metallic iron from meteoritic material. Such a form of Fe, which is nearly nonexistent on the present Earth's surface, was supposedly abundant at that time corresponding to the end of the ► [Late Heavy Bombardment](#), and there was an anoxic atmosphere. Interestingly, these authors found that whereas metal weathering occurred regardless of

the presence of iron-oxidizing bacteria, the weathering products clearly showed isotopically contrasted iron pathways during oxidation with and without bacteria. This suggests that the biological action in meteorite weathering could be highlighted with Fe isotopes (Fig. 1).

Among subsequent experimental studies, Amor et al. (2016) investigated the Fe isotope fractionation during the growth of magnetotactic bacteria and found a unique mass-independent iron isotope fractionation between the culture medium and the bacterially produced magnetites. The next challenge is to find geological formations where this effect can be recorded despite obvious risks of dilution of this isotopic signature in the rock matrix (Amor et al., 2020).

Iron Isotopes, Fig. 1 Products of iron meteorite weathering in aqueous solutions with (Biomet) and without (Abiomet) iron-oxidizing bacteria. Both the weathered layers at the surface of the meteorites (scraping) and precipitates elsewhere in the experimental cell (precipitate) were sampled. Iron isotope composition relative to the starting meteorite shows contrasted Fe isotope signatures for these weathering products with and without bacteria, suggesting contrasted reaction pathways (Error bars within symbols; From Gronstal et al. 2009)

Future Directions

Iron isotopes have not yet been applied frequently to astrobiology problems. More case studies therefore need to be investigated, either experimentally, and from natural examples of extreme terrestrial environments, or of the oldest remains of the early Earth. There are however more fundamental issues that need to be addressed first to be able to fully exploit the potential of iron isotope signatures in this endeavor. In a number of studies, equilibrium isotopic fractionation between phases is taken as a reference against which the observed natural variations may be interpreted. This is especially important in low-temperature environments where kinetic isotope fractionations are more likely to be observed given the sluggishness of chemical reactions under such conditions and therefore the large amount of time required to reach equilibrium. For this, more experimental and numerical determinations of the fractionation factors are required. It is important to conduct both approaches simultaneously since cross-validation of experimental, theoretical, and natural determinations is clearly needed (Hill et al., 2010). Another important development is the need for in situ data. Meteorites and very old terrestrial samples have had a protracted history that generated chemical and isotopic heterogeneity. Producing bulk sample data unveils only a portion of the message. Doing precise and accurate in situ Fe isotope determinations (Horn et al. 2006; Steinhöfel et al. 2010; Czaja et al. 2013) is more likely to fully unfold the history that iron isotopes can tell.

Acronyms

FeOB; Iron-oxidizing bacteria

Definition

Iron oxidation is a chemolithotrophic microbial metabolism whereby metabolic energy is generated via the removal of electrons (oxidation) from inorganic ferrous iron [Fe(II)]-containing compounds, resulting in the formation of ferric iron [Fe(III)]-containing compounds.

Overview

Prokaryotic organisms are capable of generating metabolic energy from the oxidation of Fe(II) to Fe(III), often coupled to autotrophic growth (chemolithoautotrophy) (Konhauser et al. 2011). A wide range of environments are present on Earth where microorganisms are known to participate in Fe(II) oxidation (Fig. 1). Due to the rapid rate of abiotic oxidation of soluble Fe(II) by oxygen at neutral pH (Singer and Stumm 1970), several strategies exist for iron-oxidizing bacteria (FeOB) to compete with abiotic oxidation including oxidation of soluble Fe(II) at neutral pH under low-oxygen conditions, oxidation of insoluble Fe(II) mineral phases at neutral pH, oxidation under acidic conditions, and oxidation of soluble or mineral-bound Fe(II) under anaerobic (no oxygen present) conditions. In all of

these cases, rates of the abiotic chemical oxidation are sufficiently low to allow for FeOB to utilize Fe(II) as an energy source. It should be noted that all of the examples of Fe-based microbial life described below have relevance to the potential for life on Mars.

Aerobic Iron Oxidation

At neutral pH under fully aerobic conditions, soluble Fe(II) undergoes rapid chemical oxidation and hydrolysis to form insoluble Fe(III)-(oxyhydr)oxides, limiting the availability of soluble Fe(II) for lithotrophic microbial growth. In order to efficiently compete with chemical oxidation, neutral pH FeOB such as *Gallionella* and *Leptothrix* (Emerson et al. 2010) typically inhabit zones in soils and sediments where reduced ferrous iron-containing fluids meet an overlying aerobic environment, establishing opposing gradients of Fe(II) and oxygen that allow for iron oxidation under low-oxygen conditions:

In addition to the use of soluble Fe(II) as a source of electrons, it has also been demonstrated that FeOB can use solid phase, mineral-bound Fe(II) including the structural iron in biotite (Shelobolina et al. 2012) and clay minerals (Benzine et al. 2013) for lithotrophic growth. Abiotic oxidation of these minerals at neutral pH is sufficiently slow to allow for growth of FeOB, even under fully aerobic conditions.

Under acidic conditions Fe(II) is chemically stable, and acidophilic Bacteria such as *Acidithiobacillus ferrooxidans* and *Leptospirillum ferrooxidans* (Schrenk et al. 1998) and Archaea such as *Ferroplasma* (Edwards et al. 2000) grow by oxidizing Fe(II) with oxygen as a terminal electron acceptor as in the equation above. Little thermodynamic energy is generated by this reaction; thus these organisms need to turn over large quantities of Fe(II) to obtain enough metabolic energy

Iron Oxidation, Fig. 1 Examples of environments where iron oxidation (and in some cases reduction; see “► [Iron Reduction](#)”) takes place, including the surface of a freshwater wetland sediment (panel A; E. Roden, unpublished, used with permission), the upper layer of a waterlogged soil (panel B; A. Hartemink, unpublished, used with permission), and an “oxidation/reduction” transition zone in a groundwater aquifer (panel C; reprinted (adapted) with permission from Fig. S4 in Percak-Dennett et al., *Environ. Sci. Technol.*, 2014, 48 (16), pp. 9197–9204. Copyright (2014) American Chemical Society), where Fe(II) enters from a Fe(II)-rich “reduced” zone; Precambrian banded iron formation rocks (panel D; C.M. Johnson, unpublished, used with permission) where Fe(II) from deep ocean water was oxidized in the surface ocean, ultimately leading to the formation of huge Fe-rich geological deposits; a wetland plant root zone (panel E;

adapted with permission from Fig. 1 in Shelobolina et al., *Front. Microbiol.*, 2012, Article 134) where oxygen leaked from plant roots is linked to Fe(II) oxidation; a groundwater iron seep (panel F; adapted with permission from Fig. 2 in Roden et al., *Front. Microbiol.*, 2012, Article 172) where Fe(II) in low-oxygen groundwater comes into contact with atmospheric oxygen and in which both iron oxidation and reduction are known to take place; and an acid mine drainage environment (panel G, W. Burgos, unpublished, used with permission), where Fe(II) derived from pyrite is oxidized under acidic conditions. Dashed boxes indicate zones of Fe oxidation (red arrows)/reduction (blue-green arrows) activity. The presence of both arrows indicates that both oxidation and reduction are taking place; a single vertical red arrow indicates a predominantly Fe-oxidizing environment

for growth. Commonly associated with acid rock drainage where iron sulfide minerals, including pyrite (FeS_2) are oxidized, even a small number of these microorganisms can generate significant quantities of dissolved Fe(III) and sulfate (SO_4^{2-}). This is of high environmental concern, as at extremely acidic pH (≤ 3), soluble Fe^{3+} ,

rather than oxygen, is the dominant oxidant for pyrite (Moses et al. 1987):

The primary role of acidophilic FeOB is thus to re-oxidize (according to eq. 1) the soluble

ferrous iron that is the product of the above reaction, which can again serve as the oxidant for pyrite, generating more acidity and establishing a self-propagating system.

Chemolithotrophic Anaerobic Iron Oxidation

In environments lacking oxygen, oxidants capable of receiving electrons from Fe(II) include Mn(IV) oxides and oxidized nitrogen species including nitrate and nitrite. No organisms are known to couple the oxidation of Fe(II) to Mn(IV) reduction; however chemolithotrophic oxidation of Fe(II) can occur using nitrate as the terminal electron acceptor according to the reaction (Straub et al. 1996):

In contrast to the inherent competition for Fe(II) of aerobic neutral pH FeOB, in nature Fe(II) is not spontaneously oxidized by nitrate; thus nitrate-dependent FeOB do not require mechanism to compete with abiotic oxidation pathways. While autotrophy is widespread among aerobic FeOB, most organisms that couple denitrification to iron oxidation are not autotrophic but rather mixotrophic, oxidizing Fe(II) to gain energy and assimilating preformed organic compounds for cell biosynthesis.

Photosynthetic Anaerobic Iron Oxidation

Anoxygenic photosynthetic Fe(II) oxidation, also known as photoferrotrophy, is a form of photosynthesis that does not produce oxygen (Widdel et al. 1993) and is performed by a diverse group of microorganisms including purple sulfur, purple nonsulfur, and green sulfur bacteria (Camacho et al. 2017). The generalized reaction for photoferrotrophy is:

Photoferrotrophs typically live in anaerobic environments or tolerate small amounts of molecular oxygen where chemical Fe(II) oxidation is limited. Alternatively, they may have a low requirement for light allowing them to live deeper in the water column where Fe(II) concentrations may be higher owing to proximity to a source of replenishment. While their habits are relatively restricted in a modern, oxygenated world, photoferrotrophs are postulated to have played a role in the deposition of ancient iron mineral deposits called banded iron formations in the Precambrian, prior to the oxygenation of Earth's atmosphere (Kappler et al. 2005).

Relevance to Astrobiology

NASA's Mars rover missions have shown conclusively that the surface soils of Mars, commonly known as the "Red Planet," are rich in various types of Fe(III)-bearing mineral phases that are thought to have formed under aqueous conditions early in the planet's history (Squyres et al. 2004) from oxidative weathering of Fe(II)-bearing basalt rocks that dominate the Martian crust (Foley et al. 2003). In some cases the mineralogy indicates formation under acidic conditions (Squyres et al. 2004), whereas other environments had a more neutral pH (Grotzinger et al. 2014). The wide range of Fe oxidation-based microbial metabolisms described above speak directly to the long-acknowledged possibility that oxidation of Fe(II)-bearing phases on early Mars may have been at least partially mediated by life (Jakosky and Shock 1998; Jepsen et al. 2007). Geologists and planetary scientists have speculated openly about the potential for microbial Fe oxidation to have played a role in the formation of Fe(III) oxide (hematite)-rich mineral "berries" that are abundant on the Martian surface (Chan et al. 2004; Ormo et al. 2004) and for Fe-based energy metabolism to have

taken place in ancient aqueous environments characterized by neutral pH and variable oxidation/reduction states of iron and associated elements (e.g., sulfur) in fine-grained sedimentary rocks (Grotzinger et al. 2014). Astronomical analyses suggest that at least some earth-sized exoplanets are likely to be Fe-rich “rocky” bodies (Howard et al. 2013), raising the possibility that Fe-based microbial life could exist on planets in other solar systems.

Definition

Iron oxides, hydroxides, and oxyhydroxides are commonly found minerals that contain ferrous (Fe(II)) and ferric (Fe(III)) iron, oxygen (O), and hydroxyl (OH), widespread in rocks, sediments, and soils. They are highly reactive mineral phases and their formation, transformation, dissolution, and catalytic activity are tightly coupled to various elemental cycles and pollutant transformations.

Overview

Iron oxides, hydroxides, and oxyhydroxides are ubiquitous minerals consisting of iron (Fe), oxygen (O), and hydroxyl (OH) found in rocks, sediments, and soils. There are sixteen iron oxides and oxyhydroxides (often collectively referred to as “iron oxides”) (Cornell and Schwertmann 2003). Most iron oxides contain iron in the trivalent state (Fe(III)); only three oxides – wüstite (FeO), magnetite (Fe₃O₄), and Fe(OH)₂ contain iron in the divalent state (Fe(II)). Iron oxides often occur as high surface area nanoscale mineral particles which are highly reactive (e.g., van der Zee et al. (2003)) (Fig. 1).

Iron oxides can be formed by two major pathways: (i) direct precipitation of dissolved Fe(II) or Fe(III), and (ii) transformation from another iron oxide precursor (Cornell and Schwertmann 2003; Schwertmann and Cornell 2008). Dissolved Fe (II) is rapidly oxidized to Fe(III) in the presence of oxygen abiotically at circumneutral pH values (Stumm and Morgan 1970) and microbially at acidic pH values (Blake II and Barrie Johnson 2000) (► [Fe Oxidation](#)). As the solubility of Fe (III) is very low at neutral pH, it tends to precipitate to form Fe(III) oxides. Ferrihydrite, a poorly crystalline iron oxyhydroxide (nominally given as Fe₁₀O₁₄(OH)₂, although the structure has been debated), is often the first product of neutrophilic Fe(II) oxidation and subsequent precipitation (Cornell and Schwertmann 2003). It is considered the precursor to thermodynamically more stable oxides such as goethite (α-FeOOH) and hematite (Fe₂O₃).

Transformation between iron oxide minerals may occur via solid-state recrystallization or dissolution-reprecipitation. For example, goethite is transformed to hematite under dry conditions at high temperatures (Gualtieri and Venturelli 1999). Under ambient, near-surface conditions, reconstructive transformations via dissolution and precipitation in solution are dominant; for example, the recrystallization of ferrihydrite (Fe₁₀O₁₄(OH)₂) to form goethite under reducing conditions (Hansel et al. 2003). Such transformations are suppressed in the presence of organic carbon (Chen et al. 2015) and silica (Anderson and Benjamin 1985), leading to the preservation of ferrihydrite over longer time-scales and at higher temperatures.

All iron oxides tend to sorb macronutrients such as phosphate (Wilson et al. 2004), organic carbon (Kaiser and Guggenberger 2000), and trace elements such as nickel (Jenne 1968). Ferric iron in iron oxides may be used as an electron acceptor in microbial respiration (Lovley and Phillips 1986) (► [Iron Reduction](#)), releasing these nutrients and trace elements into the surrounding water. Similarly, iron oxides may also immobilize inorganic pollutants such as arsenic (Dixit and Hering 2003) and transform organic pollutants such as TNT (Hofstetter et al. 1999). In this manner, iron oxides are tightly coupled to

Iron Oxides, Hydroxides, and Oxyhydroxides, Fig. 1 Iron oxides in natural and engineered environments. (a) Banded Iron Formation from White Mfolozi Gorge, South Africa (3 Ga). (b) Iron oxide-rich water of

the river Rio Tinto, Spain. (c) Orange iron oxide precipitates formed due to oxygenation in paddy soils of Vercelli, Italy. (d) Iron oxide-coated sand in drinking water filters used in Vietnam.

the biogeochemical cycling of several elements and the fate of different classes of pollutants.

Due to their ubiquity and reactivity, iron oxides may act as proxies for the environmental conditions they were formed under as well as post-formational environments. The presence of hematite and goethite on the surface of Mars has provided evidence for the existence of water in the planet's past (Klingelhöfer et al. 2004; Murchie et al. 2009). Observations of magnetite concurrent with Fe sulfides and Fe carbonates in the Martian meteorite ALH84001 have been hypothesized as evidence for biogenic activity on Mars (McKay et al. 1996). In addition to the mineralogy, the trace element and isotopic composition of iron oxides may also provide information about the aqueous chemistry at the time of formation. For example, trace element concentrations in iron

oxide-rich banded iron formations (Fig. 1) (► BIFs) have been used to infer marine phosphate concentrations in the Archean (Bjerrum and Canfield 2002; Konhauser et al. 2007).

Acronyms

DIR Dissimilatory iron reduction
DIRM Dissimilatory iron reducing microorganisms

Definition

Dissimilatory iron reduction (DIR) is a form of anaerobic (without oxygen) microbial respiration

whereby energy is generated by coupling the oxidation (removal of electrons) of organic matter (chemoorganotrophy) or H_2 (chemolithotrophy) to the reduction (addition of electrons) of ferric iron [Fe(III)]. DIR can be generalized by the following equations, where “ CH_2O ” represents a single unit of organic carbon, and $Fe(OH)_3$ represents an iron oxide mineral phase:

Chemoorganotrophic Fe(III) reduction:

Chemolithotrophic Fe(III) reduction:

Overview

Microbial Fe(III) reduction plays an important role in the biogeochemical iron cycle producing ferrous iron [Fe(II)] which is subject to either microbial or abiotic oxidation (see Fig. 1 in ► “Iron Oxidation”) (Emerson et al. 2012; Konhauser et al. 2011; Lovley et al. 2004; Weber et al. 2006). Furthermore, the activity of dissimilatory iron reducing microorganisms (DIRM) can help remediate metal contamination from subsurface environments. Unlike assimilatory iron reduction where Fe(III) is reduced and transported into the cell for essential biological processes, DIR occurs external to the microbial cell as a means of energy generation (Lovley et al. 2004). Organisms capable of respiring ferric iron are spread throughout multiple clades within the Archaeal and Bacterial Domains of life. Several of these microbial species, the Archaea especially, are thermophilic and hyperthermophilic organisms that appear near the root of the universal phylogenetic tree of life. This has led scientists to hypothesize that DIR is one of the most ancient modes of respiration on Earth (Vargas et al. 1998; Lovley 2004).

Iron Reduction in Modern Environments

Modern DIRM are a diverse group of prokaryotic organisms including members of the

δ -Proteobacteria such as *Geobacter* spp. and *Desulfuromonas* spp., γ -Proteobacteria like *Shewanella* spp., acidothermophiles like *Sulfolobales* and *Acidocaldus* spp., and hyperthermophilic species of *Pyrobaculum* and *Thermotoga*, to name a few (Lovley et al. 2004; Weber et al. 2006). These microbes can be found in numerous environments such as Fe seeps/springs, marine and freshwater sediments and wetlands, and hydrothermal vents (Emerson et al. 2012; Konhauser et al. 2011; Lovley et al. 2004). Typically, DIRM are restricted to the anoxic zones of these environments; however, it has been demonstrated that certain species of *Geobacter* are not only aerotolerant but can grow by O_2 respiration at low concentrations (Lin et al. 2004).

Ferric iron is insoluble at circumneutral pH, and even in acidic environments ($\sim$ pH 3) Fe(III) is predominantly in the form of Fe(III) (oxyhydr)oxide mineral phases. Ferric (oxyhydr)oxides accumulate in the environment when aqueous ferrous iron entering system is rapidly oxidized by atmospheric or dissolved O_2 , or microbial activity (see ► “Iron Oxidation” for more details). Amorphous Fe(III) (oxyhydr)oxides are the preferred form of Fe(III) for DIRM (Lovley and Phillips 1987), although other Fe (III) minerals including clays and more crystalline minerals like hematite and goethite are capable of supporting DIRM (Roden and Zachara 1996). Respiration of Fe(III) presents a problem for microbial energy generation given that in most situations, the Fe(III) used for respiration is in the form of insoluble minerals external to the cell. DIRM have evolved extracellular electron transfer (EET) mechanisms to overcome this problem. Electrons released within the DIRM by the oxidation of organic matter or H_2 are passed through a series of EET proteins in the cell cytoplasm, periplasm, and membrane(s) and ultimately deposited on Fe(III) outside the cell (Shi et al. 2016). In cases where direct cell to mineral contact is not possible, DIRM utilize soluble electron shuttling proteins (*Shewanella* spp., *Geothrix* spp.) or external cell structures called nanowires (*Geobacter* spp.) to complete the electron transfer conduit to Fe(III) (Lovley et al. 2011).

Iron Reduction on Early Earth

Aerobic respiration, the coupling of the oxidation of organic matter to the reduction of O₂, is the most energetically favorable microbial metabolism on modern Earth. However, on early Earth, electron acceptors such as O₂ existed at a fraction of the concentration we have today. Therefore, early microbial life evolved to utilize alternative electron acceptors such as ferric iron. The oceans of early Earth were anoxic and iron would have remained soluble in its reduced, ferrous, form unless acted upon by chemical oxidation, by ultraviolet radiation from the sun, or by direct or indirect microbial oxidation by photoferrotrophic or oxygenic photosynthetic organisms, respectively. The resulting Fe(III) (oxyhydr)oxide minerals that settled to the ocean floor in close proximity to hydrothermal vents would have provided microorganisms with ideal conditions to couple the oxidation of H₂-rich hydrothermal fluids to the reduction of freshly precipitated Fe(III) (oxyhydr)oxides. Elsewhere input of organic matter from photosynthetic organisms was likely available for DIRM, thereby creating ideal sedimentary conditions for Fe(III) reduction (Lovley 2004). Geologically we can see signature of this process in the deposits known as banded iron formations (Cloud 1965; Johnson et al. 2008; Konhauser et al. 2011; Konhauser et al. 2005).

Relevance to Astrobiology

Microorganisms capable of DIR inhabit diverse environments ranging from the extreme to tolerable by human standards. Scientists studying “extremophile” DIRM have gained insight into the evolution of this ancient metabolic process and the evolution of early microbial life itself. Furthermore, DIRM isolated as part of these studies have helped expand what we consider to be the habitable range for life on Earth and possibly other planets. One specific strain, a hyperthermophilic Archaeon called strain 121, is capable of growing at temperatures up

to 121 °C using Fe(III) oxides as a terminal electron acceptor for respiration (Kashefi and Lovley 2003). Indirect evidence has also suggested that DIRM expand our understanding of the physical and geological habitable zone for terrestrial life. Thermophilic DIRM have been recovered from deep subsurface environments (Roh et al. 2002) and micrometer sized magnetite grains have identified at depths of almost 7 km within the crust (Gold 1992). Magnetite is a known byproduct of DIR (Jimenez-Lopez et al. 2010), and the size and composition of the mineral has been cited as having a microbial origin. The ability of DIRM to thrive in hydrothermal and deep crustal environments raises an exciting potential as researchers consider the possibility of life beyond Earth. Along these lines, it has been speculated that magnetite and other Fe-containing minerals (e.g., siderite) detected in the Martian meteorite known as ALH84001 may have arisen from DIR activity early in Mars’ history (McKay et al. 1996). Potential energy sources for such metabolism include reduced gases such as hydrogen and carbon monoxide of both subsurface (Mumma et al. 2009) and atmospheric (Weiss et al. 2000) origin. As in the case of Fe(II) oxidation, DIR-based microbial life is a premier candidate for life on recently identified Earth-size Fe-rich “rocky” exoplanets (Howard et al. 2013).

Definition

The International Organization for Standardization is a network of national standards institutes from 165 countries. It sets standards for almost all service, industrial, and commercial activities. These standards are used as a common basis to describe activities related to space by most of the space agencies either to design instruments, rockets, and spacecraft or to manage projects. For planetary protection, these standards are used to define levels of biosafety or microbiological procedures.

Isochron

Francis Albarède
Laboratoire de Géologie de Lyon, Ecole Normale
Supérieure de Lyon, Lyon Cedex 7, France

Definition

An isochron refers to a curve or a surface that describes the state of multiple systems with the same age. In ► [geochronology](#), an isochron is a straight line describing how a particular isotopic ratio changes in response to radioactive decay. For instance, the abundance of ^{143}Nd in rocks increases

upon decay of their ^{147}Sm content. When several minerals precipitate from the same magma, their $^{143}\text{Nd}/^{144}\text{Nd}$ and $^{147}\text{Sm}/^{144}\text{Nd}$ ratios form an isochron with a slope that can be converted into an age. An isochron typically requires that all of the synchronous systems involved formed with the same $^{143}\text{Nd}/^{144}\text{Nd}$ ratio and that no Sm or Nd were subsequently lost or added.

Synonyms

[IEP](#); [pI](#)

Definition

The isoelectric point is the pH at which a molecule or surface carries no net electrical charge. Many molecules are zwitterions, containing both positive and negative charges. The net charge on the molecule is governed by the pH of the surrounding medium. The pI is the pH value at which the molecule carries no net electrical charge, and thus the negative and positive charges are equal. For a doubly charged species containing both negative and positive charges, for example an ► [amino acid](#) with only one ► [amine](#) and one carboxyl group, the pI is simply the sum of the pK_a's of the two ionizable groups divided by 2. The terms isoelectric point (IEP) and point of zero charge (PZC) are often used interchangeably, although they have subtle differences.

For surfaces, in the case when the surface charge-determining ions are H⁺/OH⁻, the net

surface charge is affected by the pH of the surrounding liquid medium. The pI then is the pH value of the solution at which the surface carries no net charge, that is, positive and negative charges are canceled out.

Many biological molecules, such as ► [proteins](#), contain both positively and negatively charged functional groups on their component amino acid side chains at physiological pH. At a pH below their pI, proteins carry a net positive charge; at pH values above their pI, they have a net negative charge.

Isoleucine

Kensei Kobayashi

Yokohama National University, Yokohama, Japan

Definition

Isoleucine is one of the 20 protein amino acids. Isoleucine's three-letter symbol is Ile and one-letter symbol is I. Its molecular formula is $C_6H_{13}NO_2$, which gives a molecular weight of 131.17. Its isoelectric point (pI) is 6.02. Isoleucine has many ► [isomers](#): one which is also present in ► [proteins](#), ► [leucine](#) (side chain: $-CH_2CH(CH_3)_2$), and 29 other isomers. Isoleucine has two asymmetric carbons: α -carbon and β -carbon, giving four ► [stereoisomers](#): L-isoleucine (Fig. 1a), D-isoleucine (Fig. 1b), L-*allo*-isoleucine (Fig. 1c), and D-*allo*-isoleucine (Fig. 1d). Only L-isoleucine is present in proteins, and it is widely distributed in the biosphere. It has been identified in extracts from carbonaceous chondrites and among the products of spark discharge experiments in gas mixtures containing methane.

Isomer

Robert Hazen

Geophysical Laboratory, Carnegie Institution of Washington, Washington, DC, USA

Definition

Isomers are molecules that have identical molecular formulas but different structural formulas. In constitutional isomers, the atoms are connected in different sequences, as in the case of the two C_2H_6O isomers, dimethyl ether (CH_3-O-CH_3) and ethanol (CH_3CH_2-OH). Similarly, butane and methyl propane (isobutane) are constitutional isomers (conformers) of C_4H_{10} . ► [Stereoisomers](#), by contrast, are molecules with identical formulas and the same atomic connectivity but which differ in their spatial arrangements. Stereoisomers can be further divided into conformational isomers (conformers), which can transform one to the other by a rotation around single bond, and configurational isomers (including chiral molecular pairs), which do not transform one to the other without breaking at least one bond.

Synonyms

Terpenoids

Definition

A diverse class of organic compounds constructed from multiple (2 to 10^3) C5 isoprene units (Fig. 1) linked into larger molecules having linear or ringed structures. Isoprenoids are ubiquitous in biology and are observed as molecular fossils in ancient bitumen, oil, and kerogens of the geological record. Isoprenoids are lipid compounds common in ► **membranes** of ► **archaea**, ► **bacteria**, and eukaryotes included in many proteins and are critical to a wide variety of cellular functions. Examples of isoprenoids include the phytol side chain of chlorophylls and diagenetic products (such as phytane; Fig. 2), squalene, biphytane, tocopherols, carotenoids, aryl isoprenoids, hopanoids, and steroids.

Overview

Formation of isoprenoids occurs via polymerization of Δ^3 -isopentenylidiphosphate (IDP), a five-carbon product of both the mevalonic acid (MVA) and non-mevalonic (also referred to as the MEP) pathways. Eukaryotes and archaea utilize the MVA pathway, while the majority of bacteria utilize the MEP pathway. Consequently, isoprenoids tend to have carbon numbers in increments of five (e.g., C20, C25, C30, C35, C40 acyclic isoprenoids of archaea or C20, C25, C30 highly branched isoprenoids of diatoms).

Isoprenoids, Fig. 1 The C5-isoprene subunit (2-methyl-1,3-butadiene) used in the biosynthesis of all isoprenoids

Isoprenoids with different carbon numbers are the result of post-synthesis modifications. The C5-incremental molecular pattern is an example of a generic biosignature resulting from a shared precursor (i.e., isoprene) used in biosynthesis. Isoprenoids and similar molecular patterns have not been observed in meteorites or experimental products of abiotic Fischer–Tropsch reactions.

Isoprenoids are distributed across different phylogenetic groups and all three domains of life, though particular compound groups are observed in association with specific organisms or environmental conditions. Among the cyclic members, the group of triterpenoids (C30) is widely distributed as hopanoids and steroids. Hopanoids are only found in ► **bacteria**, though not all bacteria synthesize them. Steroids are present in all eukaryotes. Acyclic isoprenoids are the hallmark lipids of archaea, though they are found in bacteria and eukaryotes as well. Archeol (diphytanylglycerol), caldarchaeol (dibiphytanyl – diglycerol – tetraether), C20-croctane (2,6,11,15-tetramethylhexadecane), C25-PMI (2,6,10,15,19-pentamethylcosane), biphytane, and other >C20 acyclic isoprenoids are produced specifically by archaea. The most common isoprenoids in sediments are C19-pristane and C20-phytane, which may be derived from a variety of precursor compounds including phytol of cyanobacterial and green plant chlorophylls, tocopherols from plant and phytoplanktonic, and >C20 acyclic isoprenoids from archaea. Isoprenoids are dominantly hydrocarbon skeletons with attached functional groups that are lost during diagenesis and thermal maturation leaving the hydrocarbon skeletons for potential preservation in the rock record. Given the ability for the isoprene units to join in either a head–head or a head–tail configuration, a great variety of structures can be made during cyclization. This allows the possibility of a stereochemical preference to be an additional indicator of biologic activity.

Isotope

Francis Albarède

Laboratoire de Géologie de Lyon, Ecole Normale Supérieure de Lyon, Lyon Cedex 7, France

Definition

Two ► [nuclides](#), e.g., ¹⁶O and ¹⁸O, are isotopes of the same element (here oxygen), if their nucleus has the same number of protons (same charge) but a different number of neutrons (different mass numbers). Because their electronic shells must balance the nuclear charge, isotopes have the same electronic configuration and, hence, very similar chemical properties. Isotopes can be either stable or radioactive. Stable isotopes are those

isotopes that do not spontaneously undergo radioactive decay. Radioactive isotopes are those with an unstable nucleus that stabilizes itself by emitting ionizing radiation (decay). Radiogenic isotopes are produced by the decay of radioactive isotopes. With few exceptions, even-number isotopes are more abundant than odd-number isotopes. The uncertainty principle requires the existence of a mass-dependent vibrational zero-point energy, which accounts for subtle differences in the chemical properties of the isotopes of the same element. This is the basis of the stable isotope geochemistry of light elements (H, C, N, O, S, etc.).

Definition

The term biosignature (or biomarker) *sensu stricto* refers to any physicochemical signature directly derived from the activity of living organisms, which can provide evidence for life. In geology and astrobiology, this includes stable isotope signatures measured directly on organic matter and metabolic by-products (i.e., minerals and fluid inclusions) derived from anabolic and catabolic reactions and preserved in the rock record.

Overview

In the search for biosignatures on Early Earth and beyond, the stable isotopic compositions of carbon (C), nitrogen (N), sulfur (S), and iron (Fe) are most commonly used. They can provide key information not only on the biological origin of substances, but also on the pertinent metabolic pathways of formation and degradation of organic matter and related biominerals, as well as environmental conditions at the time of deposition (see ► “Biomarkers”). They are also useful tools for reconstructing the evolution of biogeochemical cycles for a given element through geologic time. The relevance of using stable isotopes as biosignatures hinges on the fact that life fractionates isotopes in a diagnostic way that is different to other abiotic physicochemical processes. This arises from the activity of enzymes, which help organisms to drive desirable but thermodynamically unfavorable reactions by coupling them to a favorable one. In most cases, for the same reaction (same reagents and products), biotic and abiotic pathways differ strongly in the mechanism and number of steps involved, and therefore in speed, yield, and in the magnitude of stable isotope fractionation (see ► “Stable Isotopes”). Here, we review the basic methodology and present possible interpretations of stable isotope data in our search for biosignatures on the Early Earth

(see ► “Archaeal Traces of Life”). To illustrate this concept, examples for applications of established isotopic biosignatures (C, N, S, and Fe) are provided as well as limits and cautions when dealing with the biosignatures in the rock record.

Basic Methodology

The present state-of-the-art method to study isotopic compositions of any potentially biodegraded materials is isotope ratio mass spectrometry (IRMS). The principle of IRMS is based on the separation of the different isotopes of one chemical species (e.g., for nitrogen, measured as N₂ gas: ¹⁴N¹⁴N, ¹⁵N¹⁴N, and ¹⁵N¹⁵N) according to their differences in mass/electric charge ratio (*m/z*). Measurements are performed on purified gas molecules introduced directly into the IRMS (e.g., SO₂ or SF₆ for sulfur), or on a solution vaporized in a plasma chamber (e.g., Fe-HNO₃ for iron) using a multicollector inductively coupled plasma mass spectrometer (MC-ICP-MS). Micro- to nanoscale *in situ* measurements can be performed by coupling a laser (laser ablation technique) to the mass spectrometer, or by using secondary ion mass spectrometry (SIMS). Because of its design, the respective instrument (i.e., mass spectrometer) measures isotope ratios (e.g., ¹³C/¹²C, ³⁴S/³²S, ¹⁵N/¹⁴N, and ⁵⁶Fe/⁵⁴Fe for carbon, sulfur, nitrogen, and iron, respectively), with results always calibrated against an international standard (e.g., V-PDB for carbon [Craig 1957], V-CDT for sulfur [Jensen and Nakai 1962], AIR for nitrogen [Mariotti 1984], and IRMM-14 for iron [Taylor et al. 1992]) and expressed in the δ -notation as ‰ in parts per thousand (see ► “Delta, Isotopic”).

Key Research Findings

Carbon isotope ratios (¹²C/¹³C) were first measured on various terrestrial and extraterrestrial materials, for example, meteorites, sediments, plants, and oils (Nier and Gulbransen 1939; Murphy and Nier 1941). The earliest measurements demonstrate the diagnostic potential of depleted C isotope compositions in modern and fossilized

organic material relative to inorganic carbonate ($\delta^{13}\text{C} \approx 0\text{‰}$) as biological signals (see ► [“Carbon Cycle, Biological”](#)). Fundamentally, this represented the first use of an isotopic biosignature (Wickman 1941). Subsequently, Wickman (1952) and Craig (1953) showed that plants are systematically depleted in ^{13}C due to the preferential assimilation of the light ^{12}C isotope, and also that the magnitude of fractionation depends on plant ecology and fixation pathway (e.g., C_3 versus C_4 metabolisms). Following these discoveries, isotopic biosignatures were extended to other elements related to microbial metabolisms such as nitrogen, sulfur, and iron. On the Early Earth, anaerobic pathways including denitrification (see ► [“Nitrogen Cycle, Biological”](#)), dissimilatory iron reduction (DIR) (see ► [“Iron Reduction”](#)), microbial sulfate reduction (see ► [“Sulfate Reduction”](#)), and methanogenesis/methanotrophy have been identified in the rock record using the isotopic biosignature approach (for a recent review, see Lepot 2020). These biosignatures are archived in organic material (e.g., kerogen or graphite), in the bulk rock (e.g., banded iron formations, cherts, stromatolites, and microbial mats), and associated minerals formed as metabolic by-products (e.g., pyrite, barite, and Fe-(oxyhydr)oxides). Importantly, potential abiotic sources of “biological-like” signatures need to be evaluated (e.g., Guilbaud et al. 2011), as well as the extent of postdepositional alteration due to metamorphism that can overprint primary (i.e., sedimentary) isotope signatures (e.g., van Zuilen et al. 2003, 2007; Ueno et al. 2002) (see ► [“Biosignatures, Effect of Metamorphism”](#)). Accordingly, multiple sulfur isotope signatures ($^{33}/^{32}\text{S}$, $^{34}/^{32}\text{S}$, $^{36}/^{32}\text{S}$) (see ► [“Fractionation, Mass Independent and Dependent”](#)) contained in barite and pyrite from the 3.48 Ga Dresser Formation (Pilbara craton, Western Australia) have been identified to be one of the earliest and commonly accepted isotopic traces of microbial sulfur reduction (Philippot et al. 2007; Ueno et al. 2008) (see ► [“Dresser Formation, Traces of Life”](#)). Evidence for methanogenesis in lacustrine settings as early as 3.0 Ga (Lalla Rookh Sandstone, Western Australia) is based on strongly depleted $\delta^{13}\text{C}$ signatures in kerogen (Stüeken and Buick 2018).

There are inferences on earlier microbial life based on $\delta^{56}\text{Fe}$ and $\delta^{13}\text{C}$ signatures from banded iron formations and carbonates of the 3.77 Ga old Isua Supracrustal Belt (West Greenland) (Craddock and Dauphas 2011; Czaja et al. 2013; Rosing 1999) (see ► [“Isua Supracrustal Belt”](#)). However, the rock record of the Isua Supracrustal Belt has been affected by intense metamorphic and hydrothermal overprints, which cannot be ruled out to have caused such signatures (van Zuilen and Van Kranendonk 2019). Similarly, microbial life as early as 4.1 Ga ago has been proposed based on light $\delta^{13}\text{C}$ signatures found in graphite from rocks of Akilia Island (>3.83 Ga; Greenland) (Mojzsis et al. 1996), Nuvvuagittuq supracrustal belt (>3.75 Ga; Canada) (Papineau et al. 2011), Saglek Block (~ 3.95 Ga; Canada) (Tashiro et al. 2017), and Jack Hills (~ 4.1 Ga; Western Australia) (Bell et al. 2015) but were potentially formed or modified by abiotic processes during metasomatism (e.g., Lepland et al. 2011) (Fig. 1).

Applications

Isotopic Biosignatures Indicating Microbial Life on an Early Earth: Recent Studies from the Barberton Greenstone Belt

There are few low-grade metamorphosed sedimentary successions on Archean cratons which are suitably preserved for the search for Archean microbial life. The 3.6–3.2 Ga old Barberton Greenstone Belt in South Africa hosts some of these localities (see ► [“Barberton Greenstone Belt, Traces of Early Life”](#)). It contains the Swaziland Supergroup, which includes several volcanic sedimentary mixed successions of the Onverwacht Group (3.55–3.26 Ga), the Fig Tree Group, and Moodies Group (3.28–3.21 Ga) (Lowe and Byerly 2007).

In a comprehensive study of Marin-Carbonne et al. (2020), pyrites from the Mendon Formation (upper Overwacht Group) were analyzed in situ regarding their Fe and S isotope compositions. Pyrites occur within a 3.28–3.26 Ga old sedimentary section, mainly composed of black and ferruginous gray cherts, which were deposited

Isotope Biosignatures, Fig. 1 Formation of a habitable Earth and overview of earliest signs of microbial life based on isotope biosignatures. (See text for further details and references)

under quiet water conditions (Lowe and Byerly 1999; Trower and Lowe 2016). The cherts are finely laminated and show some well-preserved primary sedimentary features, but have been affected by post-diagenetic metamorphism and late fluid circulation, resulting in a number of secondary quartz, carbonate, and chlorite veins. Indeed, a combination of scanning and transmission electron microscope analyses shows that some pyrites recrystallized during post-diagenetic processes. In contrast, in situ trace element analyses imply that other pyrites were not affected by these processes, but were instead formed during sedimentary diagenesis. The authors conclude that fluid circulation caused recrystallization in some of the analyzed pyrites without significantly altering the original trace element signatures. This study shows that a careful consideration of post-

diagenetic processes is crucial in order to evaluate the reliability of isotope biosignatures. In this case, pyrites not only showed evidence for mass-independent S isotope signatures (positive $\Delta^{33}\text{S}$) but also Fe isotope signatures clustering around -1.8% and $+1\%$ in different pyrite populations. As there is no systematic change in Fe isotope signatures, which could be related to post-diagenetic overprint, the authors propose that these signatures indicate partial and total Fe reduction due to microbial DIR. This inference is supported by associated $\delta^{13}\text{C}$ signatures ranging between -26 and -32% consistent with fossil biomass. Pyrite has therefore likely been formed from iron monosulfides and elemental sulfur, the latter originating from volcanic sulfur-bearing molecules, delivered in an O_2 -free atmosphere as is indicated by positive $\Delta^{33}\text{S}$ signatures and

further processed by microbial-driven disproportionation in the sediment. Nevertheless, the investigated pyrite populations were affected later by S-rich and Fe-poor hydrothermal fluids, resulting in recrystallization and the absence of $\Delta^{33}\text{S}$ signals in the pyrite rims. In summary, the study by Marin-Carbonne et al. (2020) conclusively shows Fe- and S-based isotope biosignatures from Paleoarchean times and successfully unravels primary biological signals from later abiotic processes.

Recently, Homann et al. (2018) studied the 3.2 Ga old Moodies Group, an alluvial to shallow-marine deposit that contains fossilized terrestrial as well as marine microbial mats in its sedimentary rock record (see ► “Moodies Group, Microbial Mats”). The succession shows a transition from mainly alluvial to shallow-marine sandstones. Microbial mats are well preserved due to early silicification and low-grade metamorphism based on Raman analyses. Petrographic observations can distinguish between mats growing in fluvial-dominated and tidal-influenced environments. These different depositional environments are reflected in the carbon isotope composition of organic carbon, and in the bulk nitrogen isotope composition of selected samples. Terrestrial microbial mats show, on average, $\delta^{13}\text{C}_{\text{org}}$ values of -21.2‰ and $\delta^{15}\text{N}$ values of $+4.3\text{‰}$. In contrast, shallow-marine mats display, on average, $\delta^{13}\text{C}_{\text{org}}$ values of -27.4‰ and $\delta^{15}\text{N}$ values of $+1.8\text{‰}$. The authors conclude that these signatures reflect different biogeochemical cycling of carbon and nitrogen controlled by the depositional environment and associated microbial ecology. The C/N ratios are indistinguishable in both sediment types, suggesting that secondary metamorphic processes did not modify elements, and by extension isotope biosignatures of these sediments. In more detail, a wide range of $\delta^{13}\text{C}_{\text{org}}$ values in the marine sediments (-33.9‰ to -21.3‰) can be explained by a variety of carbon fixation pathways of, e.g., phototrophs, methanogens, and sulfate reducers, while near-zero $\delta^{15}\text{N}$ values indicate atmospheric nitrogen fixation. In contrast, carbon fixation in terrestrial sediments was likely dominated by phototrophs, as being shown by a narrow $\delta^{13}\text{C}_{\text{org}}$ range

(-23.6‰ to -17.9‰), while heavy $\delta^{15}\text{N}$ signatures indicate denitrification on land, based on the assumption that the atmosphere is a source of abiotically fixed nitrogen (Fig. 1).

Future Directions

The search for traces of microbial life in the Earth’s early rock record is continuously advanced by a better understanding of the coetaneous environmental conditions, improvements in the methodology, experimental work, and studies of modern analogues. These modern analogues include stromatolites, or other microbial mats (see ► “Shark Bay, Stromatolites of”) in restricted aqueous settings, or biological soil crusts in arid terrestrial settings. The latter have been analyzed for their bulk C and N isotope composition (Thomazo et al. 2020) and results are consistent with isotopic signatures of terrestrial microbial mats from the Precambrian (Homann et al. 2018). Importantly, these findings can be extended to astrobiology and search for microbial life on other planets, whereby current research is focused on future in situ measurements and Mars sample return missions (see ► “Mars Analogue Sites”). In this context, extreme microbial environments on Earth, e.g., hydrothermal pools in Iceland, could be used as modern analogues for biogeochemical processes and eventually help to identify isotope biosignatures on Mars (e.g., Moreras-Marti et al. 2021).

Chemical reaction · Isotope

Definition

An isotopic exchange reaction is an ion-molecule reaction that can transfer heavy isotopes between molecules at low temperatures by virtue of the zero-point energy difference between reactants and products.

Overview

An example of the isotopic exchange reactions that are very important in interstellar chemistry is the process $\text{H}_3^+ + \text{HD} \rightarrow \text{H}_2\text{D}^+ + \text{H}_2$, which is ► [exothermic](#) in the forward direction by ~ 230 K but ► [endothermic](#) by the same amount in the reverse direction. Therefore, at low temperatures, D nuclei from plentiful HD molecules, when incorporated in H_2D^+ , can be transferred to other neutral molecules by ion-molecule reactions. This can make, for example, the abundance ratio DCN/HCN in cold molecular clouds very much larger than the cosmic D/H ratio. Other ion-molecule reactions can proceed at low temperatures to fractionate astrophysical molecules in the rarer isotopes ^{13}C , ^{15}N , and ^{18}O .

Isotope fractionation

Definition

Isotopic fractionation in the ► [interstellar medium](#) refers to the result of chemical processes that selectively incorporate heavier isotopes into a molecule due to zero-point energy effects.

Overview

Isotopes are variants of an atom that contain different numbers of neutrons and hence have different mass. Thus, the element carbon has three isotopes, ¹²C, ¹³C, and ¹⁴C, containing six, seven, and eight neutrons, respectively. Naturally occurring isotopes are made through the processes that create the elements. In the Big Bang, which formed the lightest elements, H, He, Li, Be, and B, nucleosynthesis formed isotopes of all these, ¹H, ²H (D), ³He, ⁴He, ⁶Li, ⁷Li, etc. Indeed, the relative abundance observed for these isotopes, when allowance is made for their destruction since the

Isotopic Fractionation (Interstellar Medium), Table 1 Isotopic abundance ratios in the local interstellar medium (LISM). The abundance ratios are accurate to about 10%

Element	Symbol	Relative abundance in LISM
H	¹ H	1
	² H (D)	1/67,000
C	¹² C	1
	¹³ C	1/77
N	¹⁴ N	1
	¹⁵ N	1/450
O	¹⁶ O	1
	¹⁷ O	1/2,000

	³⁰ Si	1/30
S	³² S	1
	³³ S	1/138
	³⁴ S	1/22

universe was created, is one of the most powerful tests of Big Bang models. When incorporated into molecules, isotopes enable more accurate information to be deduced from astronomical observations of molecular transitions, particularly at radio, millimeter, and infrared wavelengths, as well as act as probes for stellar nucleosynthesis. Table 1 lists the isotopes of the six most common elements that have been detected in interstellar molecules, together with an estimate of their galactic abundance relative to the most abundant isotopic form. Note that these values are representative of the local interstellar medium, although some are known to depend on local star formation activity and thus vary with galactic radius and can be significantly different from values measured in the solar system.

Basic Methodology

Molecular line astronomy, that is, the observation of rotational and ro-vibrational transitions in molecules, is the main means by which we can probe the formation of stars deep in the interstellar clouds in which they are born. In particular, rotational transitions, which have energies equivalent

to a few tens of degrees Kelvin, are well matched to the kinetic temperature of the molecular gas, 10–100 K. Very high-resolution spectrometers, coupled with large surface area radio and submillimeter telescopes on dry mountain tops, such as the James Clerk Maxwell Telescope on Mauna Kea in Hawaii, have been used to detect thousands of transitions in around 150 molecules, not counting isotopologues. (An isotopologue, an “isotopic analogue,” is the name given to a molecule with one or more of its constituent atoms replaced by one of its less abundant isotopes.) When several transitions of the same species can be detected at high spectral resolution, it is possible to derive temperatures, number densities, and kinematics. These physical parameters can be most accurately determined when the emission (or absorption) line is optically thin, that is, when a transition occurring anywhere in the molecular cloud can be observed. Unfortunately, this is often not the case. The lowest rotational transitions of the most abundant molecule observed in the millimeter range, carbon monoxide (CO), are often optically thick, meaning that emission/absorption arises in the surface layers of the cloud and not from the dense core where stars are born. Isotopes allow us to overcome, to a great extent, this “black veil.” Thus, while the transitions of the most common CO isotope, $^{12}\text{C}^{16}\text{O}$, can be very optically thick, those of $^{12}\text{C}^{18}\text{O}$, commonly written C^{18}O , which is around 550 times less abundant (see Table 1), are optically thin and, despite its lower abundance, still observable in interstellar clouds.

The use of isotopologues to derive physical parameters is widespread in molecular astronomy but is less useful in determining abundances of the main isotopic species due to a process called “isotopic fractionation,” which selectively incorporates heavier isotopes into a molecule due to zero-point energy effects. We consider first the fractionation of ^{13}C in CO when the bulk of carbon is in singly ionized form, C^+ , as commonly occurs, for example, in the edges of ► [molecular clouds](#). In this case the ion-neutral isotopic exchange reaction:

is exothermic in the forward direction and endothermic in the reverse direction due to the fact that ^{13}CO has a slightly lower zero-point energy, by $\Delta E_1/k \sim 35$ K, than ^{12}CO . In steady state, the abundance ratio of $^{13}\text{CO}/^{12}\text{CO}$, $R(^{13}\text{CO})$ can be written as:

$$\begin{aligned} R(^{13}\text{CO}) &= (k_f/k_r)R(^{13}\text{C}^+) \\ &= R(^{13}\text{C}^+) \exp(\Delta E_1/kT) \end{aligned}$$

where T is the kinetic temperature of the molecular gas. Hence, at the low temperatures, ~ 20 K, expected in the outer regions of molecular clouds, the isotopic ratio in ^{13}CO can be enhanced by a factor of about 6 and at 10 K by a factor of about 30. In fact, such a large enhancement is unlikely to occur since the chemistry is more involved than described by the simple equation above. Most importantly, regions in which C^+ is abundant must be pervaded by a UV radiation field sufficiently strong to keep the bulk of carbon in ionized form. This radiation field, however, also photodissociates CO and its isotopologues. Since photodissociation of CO proceeds via absorption of line photons, CO self-shields against destruction with the less abundant isotopologues less able to shield and therefore they are destroyed faster than the main isotopic form. The detailed ratio of CO to its minor isotopes thus depends on a competition between the isotope exchange reaction, which enhances the ^{13}C content in CO, and photodissociation, which decreases it. Nevertheless, the fact remains that the ^{13}C content of CO can be larger than the underlying “cosmic” ratio, although typically by a factor of less than 2. The enhancement of ^{13}C in CO, and hence its depletion in C^+ , has consequences for other molecules that form from these species. Thus, molecules formed from CO, such as HCO^+ , will carry an enhanced ratio while molecules formed from C^+ , such as CH^+ , will carry a lower ratio. It is not just gas-phase species that can carry these anomalies. Molecules formed from CO when it freezes out on to dust grains, for example, H_2CO , CO_2 , and CH_3OH , should also have enhanced isotopic ratios in ^{13}C . The study of isotopic ratios in grain ices, or in molecules evaporated from such

ices in hot molecular core regions, thus provides a potentially powerful probe of studying how individual molecules may form on grain surfaces.

In a second case, low-temperature fractionation of ^{15}N with respect to ^{14}N can occur. For instance, cometary values of $^{14}\text{N}/^{15}\text{N}$ are typically ~ 150 , while terrestrial and protosolar values are much larger (272 and 440, respectively). In models of molecular clouds, fractionation proceeds through reactions such as:

As in the case for carbon, nitrogen fractionation occurs through ion-molecule reactions, making the chemistry of He^+ significant: the fractionation timescale in the interstellar medium is essentially dictated by the availability of the helium ion, which typically destroys those molecules with which it reacts. In regions of high He^+ abundance (e.g., regions where CO has been depleted), the production of $^{15}\text{N}^+$ initiates an enrichment of nitrogen hydrides (such as ammonia) through reactions with H_2 , starting with $^{15}\text{N}^+ + \text{H}_2 \rightarrow ^{15}\text{NH}^+ + \text{H}$ and continuing until $^{15}\text{NH}_3^+ + \text{H}_2 \rightarrow ^{15}\text{NH}_4^+ + \text{H}$. This sequence is tempered by the ortho-to-para ratio of H_2 , as discussed below, which can affect the circulation of $^{15}\text{N}^+$ back into N_2 via reaction (4). Nitriles are fractionated via reaction (3). The disparity between $^{14}\text{N}/^{15}\text{N}$ ratios for CN and HCN in comets is further evidence for HCN not being the sole parent of CN in these environments.

Key Research Findings

Since isotopic fractionation occurs due to zero-point energy differences, the biggest effect occurs

in the exchange of D and H since this causes the largest increase in reduced mass in a molecular system. Indeed, enhancements of up to 10 orders of magnitude are seen in some deuterated molecules, about 30 of which have been detected in interstellar clouds, including doubly and triply deuterated species. In cold dense clouds, the reservoirs of D and H are HD and H_2 , with an underlying ratio $R(\text{HD}) = 2R_D \sim 2-3 \times 10^{-5}$, where R_D is the cosmic ratio of D to H, $\sim 1-1.5 \times 10^{-5}$. The most important isotopic exchange reaction in these clouds is the reaction of H_3^+ , formed by the cosmic-ray ionization of H_2 , with HD:

where the precise value of the exothermicity, ΔE_5 , has contributions from both enthalpy and entropy and depends on the rotational energies of the reactants. For all species in their ground states, $\Delta E_5/k \sim 230\text{ K}$. Assuming steady state, then the abundance ratio of $\text{H}_2\text{D}^+/\text{H}_3^+$ becomes:

$$R(\text{H}_2\text{D}^+) = R(\text{HD}) \exp(\Delta E_5/kT).$$

For a gas temperature of 10 K, one sees that the theoretical enhancement of the cosmic ratio, R_D , becomes extremely large as the rate coefficient of the reverse reaction in Eq. 5 goes to zero. In fact, the enhancement does not grow exponentially large at low temperatures because other reactions destroy H_2D^+ , including dissociative recombination with electrons and proton or deuteron transfer with neutrals, and act to limit the ratio. Taking these reactions into account gives a crude estimate of the enhancement factor, $S(T)$, as:

$$\begin{aligned} S(T) = 1 / \Big[&\exp(-\Delta E_5/kT) + (k_e/k_f)f(e) \\ &+ (k_M/k_f)f(M) \Big] \end{aligned}$$

where k_f is the forward rate coefficient of reaction Eq. 5, k_e is the dissociative recombination rate coefficient of H_2D^+ , and k_M is the rate coefficient for reaction of H_2D^+ with neutral species M. Here, $f(X)$ represents the fractional abundance of

species X relative to molecular hydrogen. Typically, the value of k_e is about 100 times larger than those of ion-neutral reactions. The enhancement obtained thus depends not only on the temperature but also on the relative abundances of electrons and reactive neutrals. Since the value of $f(e)$ is two to three orders of magnitude less than that of $f(M)$ in molecular clouds, it is reactions with M that determine the level of enhancement below 20 K. In fact because of its low proton affinity, H_3^+ (and H_2D^+) reacts with almost all neutral species in molecular clouds, with the exception of H, H_2 , He, N, and O_2 . For the case in which neutral abundances, $f(M)$, have their maximum values, given by the elemental abundances of C, N, and O, enhancements of up to 1,000 can occur. For the case where abundances are decreased by 100, to simulate freeze out on to cold grain surfaces, enhancements greater than 10,000 can occur, that is, $R(H_2D^+)$ can be larger than unity. For temperatures greater than about 25 K, the first term in the denominator dominates, and the enhancement falls off exponentially with increasing temperature.

Such large enhancements in the deuterium fractionation in H_2D^+ are transferred to other molecules through deuteron transfer, which is assumed to occur statistically in one-third of all reactive collisions. Thus, DCO^+ and N_2D^+ , for example, should show – and indeed do show – extremely large enhancements in cold, dense cores that have undergone some depletion of molecules, the most important of which is CO because of its large underlying abundance, on to grain surfaces.

In cases where such depletion is enhanced, the formation of doubly and triply deuterated molecules becomes possible. In the equation above for the enhancement of H_2D^+ , the species M implicitly includes HD since H_2D^+ (and D_2H^+) can also react with this species.

where the exothermicities have the same dependencies as ΔE_5 and values of ~ 187 K and 159 K,

respectively. One sees that, in certain circumstances – very low temperatures and heavy depletion of neutral species – D_3^+ can be more abundant than H_2D^+ and therefore potentially a more important deuteron donor since it transfers a deuteron on every reactive collision. In regions characterized by such conditions, corresponding to the gas in star-forming regions immediately before nuclear burning in protostars commences, observations of molecular line emission from H_2D^+ and D_2H^+ , both of which have a small electric dipole moment, may be the only feasible means of studying the physics of star formation.

Gas-phase chemistry initiated by these and other fractionation reactions drives very efficient enhancements in deuterium. For example, triply deuterated ammonia has been observed with an abundance relative to normal ammonia of $\sim 10^{-3}$, some 11 orders of magnitude greater than the statistical ratio. A similar effect is found in triply deuterated methanol, while the D_2CO/H_2CO abundance ratio has been measured to be as large as 0.4 in some clouds. While gas-phase reactions involving the deuterated versions of H_3^+ are important, grain surface reactions may also play a significant role in enhancing isotopic fractionation – it is noteworthy that the molecules showing the largest deuterium fractionation, NH_3 , H_2CO , and CH_3OH , are all thought to form efficiently in cold ice mantles on dust grains. The large fractionation in H_3^+ gives rise, upon dissociative recombination with electrons, to a large enhancement in atomic deuterium. Collisions of atomic D with cold grains then lead to an enhancement of D/H on grain surfaces and to enhancements in the species that form there.

The effect of considering the ortho and para states of H_2 can be significant (ortho signifying aligned nuclear spins and para signifying anti-parallel spins of the hydrogen nuclei). In cold interstellar environments, the zero-point energy difference between the nuclear spin states of H_2 (about 170 K) is enough to allow some slightly endoergic reactions, for example, that with N^+ , to proceed with H_2 in its $J = 1$ (ortho) state. Following on from this, if the ortho-to-para (OPR) ratio is high (i.e., the higher energy

state is dominant), production of H_2D^+ in reaction (5) can be inhibited, and the D/H ratio in H_3^+ can be lower than expected. Typically, this ortho-to-para ratio is 3 at high temperatures. Ortho to para conversion, however, occurs efficiently at low temperatures in the interstellar medium, for example, via $\text{H}^+ + \text{o-H}_2 \rightarrow \text{H}^+ + \text{p-H}_2$, meaning that in the diffuse ISM, the OPR is about 1.

Isotopic Fractionation (Planetary Process)

Francis Albarède

Laboratoire de Géologie de Lyon, Ecole Normale Supérieure de Lyon, Lyon Cedex 7, France

Definition

The term *isotope fractionation* refers to subtle variations of isotopic abundances among coexisting solids, liquids, and gases. It can both take place at equilibrium and reflect kinetic effects. It can be mass dependent, when its amplitude is a monotonic function of the isotope masses, or else be mass independent. It is normally given in delta (δ) units, which represent the relative deviation of a particular isotopic ratio in a particular sample with respect to this ratio in a reference material.

History

American physical chemist Harold C. Urey (1947) and chemists J. Bigeleisen and M.G. Meyer (1947) must be credited for the first theoretical prediction of isotopic fractionation. J. M. McCrea (1950) calibrated the fractionation of ► [oxygen isotopes](#) between coexisting carbonates and liquid water.

Overview

Isotope fractionation results from slightly different chemical properties among the isotopes of the same element. These variations are large enough (typically 0.1–10‰, where ‰ indicates permil) to be measured by mass spectrometry. They occur both at equilibrium and under the effect of kinetics. The isotopic properties of a molecule reflect its share of the different sorts of energy: translational, rotational, and vibrational. Isotope fractionation results from the Heisenberg uncertainty principle: the separation distance between two bonding atoms (e.g., O and H in OH) cannot be

that of the potential energy minimum as both the position and the velocity would be fixed. The minimum of vibrational energy is reached for the mass-dependent *zero-point energy* $\frac{1}{2} h\nu$, where h is the Planck constant and ν the vibration frequency. There is no zero-point energy for rotational energy, and the incidence of zero-point translational energy is negligible. Because vibrational energy varies inversely with the square root of the mean mass of the vibrating pair (heavy atoms vibrate less rapidly than light atoms), such an effect is referred to as *mass-dependent isotope fractionation*. Heavy isotopes prefer the low-energy states, which explains why liquid water is preferentially enriched in ^{18}O and ^2H (also represented with the notation “D”) over ^{16}O and H, respectively. Likewise, oxides (CO_2 , NO_2 , SO_2) tend to concentrate the heavy isotopes at the expense of the corresponding reduced species (CH_4 , NH_3 , H_2S). The symmetry of interacting molecules also plays a major role.

Isotopic variations of H, O, C, N, and S are commonly reported in the delta (‰) notation, e.g., $\delta^{18}\text{O}$, which is the relative excess of ^{18}O over ^{16}O in a particular sample with respect to a reference material (see Delta Notation entry).

Isotope fractionation varies with temperature, e.g.,

$$1000 \ln \alpha^{18\text{O}}(\text{quartz/water}) \\ \approx \delta^{18}\text{O}_{\text{quartz}} - \delta^{18}\text{O}_{\text{water}} = A/T^2 + B$$

where T is in Kelvin, $\alpha^{18\text{O}}$ is the ratio of $^{18}\text{O}/^{16}\text{O}$ in coexisting quartz and water, and A and B are constants (most often B is zero). Isotope fractionation is therefore most noticeable at ambient temperatures and is still significant in the crust ($<600^\circ\text{C}$). Isotope fractionation is greatly enhanced by distillation processes. Fractionation during analysis is often referred to as *mass bias*.

Understanding biological and physical isotopic fractionation processes is fundamental for discriminating the isotopic signature of elements such as C, N, S, and Fe preserved in the rock record and deciphering whether these signatures have a biological or abiological origin. Isotopic fractionation is also important for discriminating

sources of elements in the universe. An important astrobiological example is the D/H ratio (the isotopic ratio between [▶ deuterium](#) and hydrogen), which varies in hydrogenated molecules preserved in planetary bodies depending on the temperature at which water molecules exchange between a vapor and a solid phase. The D/H ratio is a valuable marker of the carrier phase of water on Earth (comets vs. meteorites), because these different bodies formed and hydrated at different distances from the Sun.

There is considerable discussion at this time about whether different planets have the same isotope abundances, notably for metals. The abundance of neutron-rich isotopes, such as ^{48}Ca , ^{54}Cr , and ^{50}Ti , clearly varies across the Solar System, but the isotope proportions of other elements such as Zn and Rb may vary as well. It is now believed that these isotope heterogeneities predate the formation of the Solar Nebula. For many elements, isotope abundances in the Moon and the Earth differ from those of [▶ chondrites](#). The Moon and the Earth have comparable isotope compositions for most elements, except for the element Zn. This issue is the topic of active research.

Isotopic Ratio

Francis Albarède
Laboratoire de Géologie de Lyon, Ecole Normale Supérieure de Lyon, Lyon Cedex 7, France

Definition

Isotopic ratio refers to the ratio of the atomic abundances of two isotopes of the same element, e.g., $^{18}\text{O}/^{16}\text{O}$ or $^{143}\text{Nd}/^{144}\text{Nd}$. An advantage of using ratios rather than absolute abundances of a particular nuclide is a better precision. Comparing the two signals ^{143}Nd and ^{144}Nd can be done at the ppm (one part in one million) precision level, i.e., two to three orders of magnitude more precisely than the counting of either nuclide individually.

Isotopic ratios change as a result of (1) thermodynamic fractionation, (2) radioactive ingrowth, (3) the presence of nucleosynthetic compounds, and (4) spallation reactions. Ratios of a radiogenic isotope (e.g., ^{143}Nd) to a stable isotope (e.g., ^{144}Nd) are used in geochronology and provide information on the geochemistry of sample source environment; ratios of stable isotopes provide information about temperatures and sources.

Isotopolog

Steven B. Charnley
Solar System Exploration Division, Code 691, Astrochemistry Laboratory, NASA Goddard Space Flight Center, Greenbelt, MD, USA

Definition

Isotopologs are molecules that differ only in the isotopic composition of their constituent atoms, for example, HDO and H₂O, where D (deuterium) is ^2H . Astrochemists sometimes use isotopomer as a synonym for isotopolog, although chemists normally define isotopomers to mean ► [isomers](#), which have the same number of each rare-isotopic atom but with these atoms differing in their positions in the molecule.

Synonyms

[Isotopic isomer](#)

Definition

Isotopomers (the term being a contraction of *isotopic isomer*) are chemical compounds (molecules, ions, radicals, etc.) that have the same number of each isotopic atom (same isotopic formula) but differ in the positions of isotopes. They are either *constitutional isomers* (e.g., $\text{CH}_3\text{-CDH-CH}_3$ vs. $\text{CDH}_2\text{-CH}_2\text{-CH}_3$), or *isotopic stereo-isomers* (e.g., (*R*)- vs. (*S*)- $\text{CH}_3\text{-CHDOH}$, or (*E*)- vs. (*Z*)- $\text{CH}_3\text{-CH=CHD}$). An isotopomer should not be confused with an *isotopologue* (a compound with the same chemical structure but with a different isotopic composition). For International Union of Pure and Applied Chemistry official definitions, see Minkin (1999) Glossary of terms used in theoretical organic chemistry. Pure Appl Chem 71:1919–1981.

Definition

Isovaline is an α -amino acid that rarely participates in biochemical processes. It has been detected in the Murchison and other meteorites, in many instances with a significant L-enantiomeric excess. It is an isomer of the biologically important amino acid valine. It has been proposed that it is synthesized prebiotically via a ▶ [Strecker synthesis](#) from methyl ethyl ketone and ammonium cyanide. Since the α -proton in isovaline is replaced with a methyl

group, the kinetics of aqueous ▶ [racemization](#) are extremely slow, and thus it has been suggested that the ▶ [enantiomeric excess](#) of L-isovaline represents an initial chiral synthetic bias, which has subsequently been lost in the α -proton containing ▶ [amino acids](#). Isovaline is, however, found in some fungal antibiotic peptides; thus, it cannot be considered a strict marker of abiological synthesis.

Definition

India began space activities in the early 1960s as a nonaligned country. Various committees were created to support the national effort in developing launchers and satellites. In 1969, ISRO was created as part of the Nuclear Energy Department and became an independent organization in 1972. In 1975, the program launched Aryabhata, the first Indian satellite, and since then, it has produced the Polar Satellite Launch Vehicle (PLSV) to launch satellites for remote sensing. The Geosynchronous Satellite Launch Vehicle (GSLV) is able to send up to 2 t in geosynchronous transfer orbit. In 1984, an Indian astronaut flew on board the Russian Salyut 7 space station. India is now turning to space sciences and

exploration, and current ISRO activities are spread among more than 20 laboratories or centers across India. In 2008, India sent the Chandrayaan-1 to orbit the Moon, and in 2014, India's Mars Orbiter Spacecraft successfully achieved an orbit around Mars.

Definition

The International Space Science Institute (ISSI) was established in 1995 as an institute of advanced studies where scientists from all over the world meet in a multi- and interdisciplinary setting to reach out for new scientific horizons. The institute organizes workshops as well as working groups and forums. Thereby, the institute offers space to scientists, ground-based observers, experimenters, theoreticians, and modelers, providing opportunities to work together and to analyze and compare data from a multitude of sources. Because data are collected from a variety of spacecraft and ground-based facilities, interdisciplinary meetings enable scientists to extract or create more science with little additional expenditure. More than 6200 individual scientists from 60 countries have participated in ISSI activities during the first 25 years of its existence and published the results in scientific publications. The institute is managing several publications

covering all the fields of space sciences, among others, the Space Sciences Series of ISSI (SSSI) and the ISSI Scientific Report Series.

The institute is based in Bern (Switzerland). The staff is headed by an executive director and includes three additional scientific directors and five scientists. The present permanent staff is around 15 people.

Strategies of Life Detection, O. Botta, J. Bada, J. Gómez Elvira, E. Javaux, F. Selsis, R. Summons (Eds.), published in August 2008, and Geology and Habitability of Terrestrial Planets, K.E. Fishbaugh, P. Lognonné, F. Raulin, D.J. Des Marais, O. Korablev (eds.), published in September 2007, are two examples of early activities of ISSI related with astrobiology.

Overview

Following the first International Conference on the Origin of Life on Earth held in 1957 in

Moscow organized by A. I. Oparin under the auspices of the International Union of Biochemistry and the second international conference held at Wakulla Falls, USA, with the support of ► [NASA](#) and Institute for Space Biosciences of the Florida State University. during the 1970 conference that took place in Pont-à-Mousson, France, the organizational meeting for the founding of the International Society for the Study of the Origin of Life (ISSOL) took place. Its first president was the Soviet scientist Alexander I. Oparin whose work during the first half of the twentieth century opened the possibility of transforming the study of the origin of life from mere speculation into a workable research program capable of unifying disparate facts and observations from widely different fields within a coherent explanatory framework provided by a Darwinian view.

Although numerous origin of life meetings had been held following the 1957 Moscow conference, most of them had a regional character and limited scope. Because of this, it was decided that the first ISSOL meeting, which took place in 1973 in Barcelona, was also named the 4th International Conference on the Origin of Life. The recognition of the scientific significance of the field of astrobiology, as promoted by NASA and adopted by scientists in many countries, led in 2005 to a change of name which transformed the society into ISSOL: The International Astrobiology Society.

ISSOL currently has some 500 members from more than 20 countries, two of whom received Nobel Prizes in 2009, Jack W. Szostak in Physiology and Medicine and Ada Yonath in Chemistry. The society's official journal is *Origins of Life and Evolution of Biospheres (OLEB)*.

Definition

The Isua supracrustal belt is the largest contiguous complex of Eoarchean supracrustal rocks (formed at or near the Earth's surface) known on Earth. It is located ca. 150 km NE of Greenland's capital Nuuk, in West Greenland.

History

Since the establishment of the Geological Survey of Greenland in 1946, geological investigations of West Greenland shifted gradually from investigations of individual mineral deposits to mapping of the general geology. By the early 1970s, the main framework of West Greenland's geology was laid

out. An orogenic belt was identified around 66°N, the so-called Nagssuqtoqidian orogen, characterized by Paleoproterozoic penetrative deformation and metamorphism of a preexisting Precambrian basement, still preserved toward the south (Noe-Nygaard and Ramberg 1961; van Gool et al. 2002). South of 61°N, the old basement was again overprinted by deformation and metamorphism during the Paleoproterozoic and the accretion of a juvenile magmatic arc onto the old continent. This Ketilidian orogen also hosted the alkaline Gardar igneous province (Ussing 1912; Garde et al. 2002) emplaced around 1,300 Ma ago (Vanbreem and Upton 1972). The Archean cratonic basement sandwiched between these two orogenic belts is known as the Archean Block.

The Achaean Block is dominated by Eoarchean and Meso-Neoarchean amphibolite and granulite-facies felsic gneisses (Bridgwater et al. 1970; Griffin et al. 1980). The gneiss complex around Nuuk (previously Godthåb) can be divided into two domains based on the presence or absence of a suite of mafic dikes named Ameralik dikes (McGregor 1968) that contain characteristic plagioclase megacrysts. The so-called Amitsoq gneisses contain mafic dikes or mafic enclaves that represent deformed fragments of such dikes. The other gneiss suite, named the Nuuk (or Nûk) gneisses, contains no Ameralik dikes and was inferred to have been emplaced later than the intrusion of the dikes (McGregor 1973). In 1971,

a suite of the ► [Amitsoq gneisses](#) was dated and produced an age of 3,650 Ma (Black et al. 1971). This exceeded by far any age obtained on terrestrial material before and established the Nuuk area as home to the oldest rocks known on Earth. The two gneiss domains turned out to be dominated by gneisses with ages centered around 3,600 Ma for the Amitsoq gneisses (Moorbath et al. 1972; Baadsgaard 1973, 1976) and around 3,000 Ma for the Nuuk gneisses (Pankhurst et al. 1973). Both gneiss complexes also contain inclusions and contiguous belts of supracrustal rock (rocks formed at or near the Earth's surface). In both terranes, the supracrustal rocks appeared to pre-date the gneisses, because the granitoid precursors to the gneisses were commonly intrusive into the supracrustal rocks. The supracrustal assemblage in the Amitsoq gneisses was named the Akilia association, and the supracrustal rocks within the Nuuk gneisses were called the Malene supracrustals (McGregor 1973; Gill and Bridgwater 1976).

During the late 1960s, prospectors carried out aeromagnetic surveys of the west coast of Greenland and identified a strong magnetic anomaly at Isua near the margin of the Inland Ice 150 km NE of Nuuk (Kurki and Keto 1966) (Fig. 1). This anomaly turned out to be caused by a large deposit of quartz-magnetite banded-iron formation (BIF). Mapping showed that the BIF formed part of a large arcuate belt of supracrustal rocks some

Isua Supracrustal Belt,

Fig. 1 The Isua landscape is barren with excellent exposure due to the high elevation and the proximity to the Greenland Ice Cap. The mountain peak in the background is “Iron Mountain,” a large quartz-magnetite banded-iron formation deposit

30 km in length and up to 4 km in width (Bridgwater and McGregor 1974; Allaart 1976). The Isua BIF gave an age of 3,770 Ma (Moorbath et al. 1973), the oldest age obtained for any rock on Earth at that time. From field relations, the Isua supracrustals and the Akilia association occupy the same chronostratigraphic position since both are older than the enveloping Amitsoq gneisses. Further isotopic age determinations supported this observation and showed that at least some of these supracrustal rocks are more than 3,800 Ma old (Baadsgaard et al. 1984; Nutman et al. 1984, 2002).

The collage of tectonic panels of different ages and origins in the Nuuk region has been placed into a model of Archean terrane accretion by Nutman et al. (1989). The oldest assemblage of rocks, which included the Amitsoq gneisses and the Isua and Akilia association of supracrustal rocks, was defined as the Itsaq Gneiss Complex (Nutman et al. 1996, 2000, 2002). Eoarchean rocks with ages >3,600 Ma have also been identified along the northern boundary of the Archean Block in the so-called Aasivik terrane (Rosing et al. 2001), but little is known about this terrane at present.

Overview

The scientific attention paid to the Eoarchean complexes around Nuuk and the Isua and Akilia supracrustals is probably unparalleled in the world of geology. The research has focused on two main avenues. One was the state of chemical differentiation of Earth by the Eoarchean, and the other was the characterization of the early Earth's surface environments and the search for traces of life on the young planet.

Early Earth Differentiation

Earth has undergone continued differentiation (see ► [“Earth, Formation, and Early Evolution”](#)) into distinct chemical reservoirs such as the granitic continental crust, the basaltic oceanic crust, the depleted mantle from which the crust was extracted and the atmosphere and the oceans where the volatile components from the depleted

mantle are concentrated. The Amitsoq gneisses and the Isua and Akilia supracrustal rocks became a prime target for the development and use of isotopic tracers to document the timing and extent of differentiation of the young Earth. If radioactive mother isotopes and their radiogenic daughter isotopes have different compatibilities in the mantle during melting, the timing and extent of melting will be reflected in the isotopic composition of both the residual mantle and the rocks formed from the melt, and the isotopic dissimilarity will be more pronounced with time. Given this insight, a number of isotopic systems were applied (see ► [“Geochronology”](#)) on Isua rocks to establish the extent and history of differentiation of Earth (see ► [“Earth, Age of”](#)) by the earliest Archean (U-Th-Pb (Moorbath et al. 1975), ^{147}Sm - ^{143}Nd (Hamilton et al. 1978), Lu-Hf (Blichert-Toft et al. 2000), La-Ce (Shimizu et al. 1988), ^{146}Sm - ^{142}Nd (Boyet et al. 2003; Caro et al. 2003). The conclusions drawn from these isotope studies were that there still was some chemical heterogeneity inherited from early differentiation of Earth preserved in the mantle at Isua time. These heterogeneities could have been established during an early magma ocean episode and subsequently progressively erased by mantle convection and back mixing of protocrust into the mantle. Another conclusion was that a depleted mantle reservoir similar to the present-day source of mid-ocean-ridge basalt was present even during the earliest Archean.

Traces of Life and Early Earth Surface Conditions

Already in 1979, the German geochemist Manfred Schidlowski (Schidlowski et al. 1979) proposed that the ratio between the two stable isotopes of carbon ^{13}C and ^{12}C found in ancient sedimentary rocks could be used to identify the presence of life in Earth's early oceans. This is because living organisms incorporate ^{12}C more efficiently than ^{13}C when they form organic matter from ambient CO_2 and therefore leave the ocean and atmosphere enriched in ^{13}C and organic-rich sediments depleted in ^{13}C . He used this principle on carbonate rocks and graphite from Isua under the assumption that the carbonate

represented the carbon isotopic composition of the early Archean ocean and the graphite represented metamorphosed organic matter (Schidlowski et al. 1979). Later geologic studies at Isua, however, showed that the carbonates were formed from circulating brines during metamorphism and that the graphite studied by Schidlowski was also secondary in origin (Rosing et al. 1996). The search for traces of early life in the Archean of West Greenland continued. In 1996, Mojzsis et al. reported the presence of ^{13}C -depleted graphite inclusions from apatite crystals in the supracrustal rocks from Akilia Island, near Nuuk (Mojzsis et al. 1996). In 1999, Rosing reported that shales from Isua contained abundant sedimentary ^{13}C -depleted carbon (Rosing 1999; van Zuilen et al. 2003) (Fig. 2). There has been an ongoing and continued controversy over the credibility of these claims for the presence of life during the earliest part of Earth's history, and research into this topic is still ongoing along many different avenues of study.

The Isua supracrustal sequence also carries information about the surface conditions on the young Earth. Most significantly, water-lain sediments attest to the presence of a liquid hydrosphere, most probably the existence of oceans, from at least 3,800 Ma ago. The Isua supracrustal rocks have also been analyzed for traces of the so-called ► **Late Heavy Bombardment**, which cratered the Moon, and possibly also affected

Earth in a dramatic way at the time of deposition of the Isua sediments. However, this search has given no clear evidence for extraterrestrial material in the Isua rocks (Schoenberg et al. 2002; Frei and Rosing 2005).

The Composition of the Isua Supracrustal Belt

Soon after the discovery of the Isua supracrustal belt, several lithologic units were identified (Keto and Kurki 1967; Allaart 1976). The belt is outlined in the field by a prominent erosion-resistant ridge, which is dominated by a chloritic amphibolite unit characterized by a distinctive amphibole sheave texture. This unit was called the Garbenschiefer Formation, and its protolith was generally believed to be a sill-like mafic intrusion. The BIF that originally had given the supracrustal belt away forms a very large body at the northeast termination of the belt under the Inland Ice, but this unit can also be traced more or less continuously along the full extent of the belt. In early maps, this BIF was lumped with various other lithologies into a "quartzitic sequence." Bordering on the BIF is a thick unit of carbonate and calc-silicate-rich rock which commonly grades into carbonate-rich mica schists. This unit was called the carbonate formation and was believed to represent a change in sedimentary facies in the same sedimentary basin that gave rise to the BIF. Along most of the length of the belt, felsic schists and two-mica gneisses are common. At many localities, these

Isua Supracrustal Belt,

Fig. 2 Well-preserved Bouma sequence with alternating graphite-rich black shale and gray turbidite sediments. The black shale contains abundant fine particles of carbon with $\delta^{13}\text{C} \sim -25$, most likely derived from living organisms

rocks display a diamictic structure. At one locality, large felsic “boulders” stand out from a slightly darker, carbonate-rich matrix. This rock was called the “bomb rock,” and fiamme-like textures were described from the alleged felsic volcanic bombs. For this reason, this felsic formation was believed to be dominated by volcanic rocks. Along the margin of the belt, black amphibolite forms the predominant lithology and was often referred to as the amphibolite formation. The distribution of lithologies gave the impression of a sequence of lithologies that was repeated by folding along an arcuate axial plane tracing the center of the supracrustal belt. It was assumed that the belt formed a rim syncline enveloping a central gneiss dome, following the style that was seen in the classical granite-greenstone terranes of Australia (Keto and Kurki 1967). Another prominent suite of lithologies is ultramafic rocks, which occur as serpentinites, talc-anthophyllite-magnesite schists, and dunites. These rocks occur as discontinuous layers and lenses within the sequence and do not appear as a single unit. In the northeastern termination of the belt, the distinctive garbenschiefer unit (see above) also occurs in a separate splay along the inner perimeter of the belt and is separated from the rest of the belt by a distinctive topographic lineament. This was considered a separate segment of the belt, which also included a mica schist unit and a felsic unit. The formations of the main belt were allocated to a so-called A sequence, and the rocks in the small separate domain were allocated to a “B sequence.” This understanding of the geology of Isua permeated the literature (Nutman et al. 1984) and formed the basis for the 1:40,000 geological map published by the Geological Survey of Greenland in 1986 (Nutman 1986). Many of the main features of the belt were surprisingly well understood in these very early works, and the main lithological subdivision has remained almost unchanged during the more than 40 years passed since the discovery of Isua. In terms of describing the makeup of the Isua belt, subsequent work has mainly proposed new interpretations of the protoliths to the present lithologies and increased the detail of their geochemical description.

Metamorphism, Deformation, and Metasomatism

It was readily observed that the rocks at Isua were generally strongly deformed (James 1976) and had experienced penetrative amphibolite-facies metamorphism (Allaart 1976; Gill and Bridgwater 1976; Nutman et al. 1984). The contact between the orthogneiss complexes that envelop the belt was identified as predominantly tectonic, and it was concluded that a suite of mafic dikes that transect both the Isua supracrustals and the gneisses were equivalent to the Ameralik dikes defined in the Godthaabsfjord region. Boak and Dymek (1982) presented a detailed study of the metamorphic overprint on the supracrustals. With increasing intensity of geochemical studies of the supracrustals and especially the advent of new isotopic tracers and age determination protocols, it became increasingly obvious during the 1970s and 1980s that many lithologies had not remained closed geochemical systems during deformation and metamorphism. It was first noted that alkali metals had been mobile (Gill and Bridgwater 1979; Baadsgaard et al. 1986), but also the Sm-Nd and Lu-Hf isotopic systems showed clear signs of disturbance (Gruau et al. 1996; Frei et al. 2002; Polat et al. 2003). Rosing et al. (1996) proposed that the Isua supracrustals had been pervasively metasomatized and that the carbonate-calc-silicate formation was not a stratigraphic unit of sedimentary origin, but rather represented a wide variety of different lithologies transformed by transient silica-undersaturated carbonic fluids derived from devolatilization reactions in the ultramafic rocks (Rosing and Rose 1993; Rose et al. 1996). Inherent in this reinterpretation of the lithologic variation within the supracrustal belt was the breakdown of the interpretation of the Isua belt as a tight syncline folded into an open arc, as the symmetry of formations about a central axial plane trace was no longer apparent when the metasomatic overprinting was considered.

Recent developments in the understanding of the tectonic construction of the Isua belt include the proposal that the Isua belt formed as an accretionary complex, which shares many similarities with the Phanerozoic accretionary complexes of

Isua Supracrustal Belt,
Fig. 3 Pillow structure in metabasalt from Isua. The pillow basalts occur in association with sheeted dikes, gabbros, and ultramafic rocks in an assemblage similar to modern ophiolite complexes

Japan (Komiya et al. 1999). This suggestion allowed for the realization that the Isua belt might be composed of tectonic panels of slightly different early Archean ages and origins (Nutman et al. 1997) and that the package included ocean-floor sequences similar to Phanerozoic ophiolites (Furnes et al. 2007) (Fig. 3). A new updated 1:20,000 geologic map constructed on the basis of a composite origin of the Isua supracrustal belt has been presented by Nutman and Friend (2009).

[ISA](#)

Definition

The Italian Astrobiology Society (SIA) was founded in 2006 by a team of astronomer,

biologist, chemist, geneticist, and medicine scientists with the scope to promote scientific research on astrobiology in Italy. The SIA is a non-profit scientific association of researchers cultivating the study of the origin, evolution, and distribution of life in the Universe. The SIA has a national and independent nature free from any government, organization, or political party. It is open to every expert with documented scientific interests in astrobiology.

The main objectives of SIA are:

- To promote the progress of Astrobiology knowledge
- To promote and coordinate the fundamental and applied research
- To stimulate the collaboration between various scientific disciplines
- To promote and favor the relationships with other international organizations
- To set up relationships with analogous associations
- To favor the development of new technologies for terrestrial and space applications
- To promote new methods of searching for signs of life
- To promote and coordinate activity of higher educations
- To promote meetings and conferences
- To favor the sharing of knowledge for educational aims
- To preserve the scientific interests of astrobiology

Itokawa Asteroid

Anny-Chantal Levasseur-Regourd
Sorbonne Univ., Campus P. & M. Curie /
LATMOS, Paris, France

Synonyms

[Asteroid 25143](#)

Definition

Itokawa (25143) is a near-Earth stony (S-type) asteroid. This object has been the first asteroidal target for a sample return mission, the ► [JAXA Hayabusa](#) mission. Itokawa is likely a contact binary. It is small (major axes 530 m, 290 m, and 210 m) and has a rotation period of about 12.13 h. Its density is rather low ($\approx 1950 \text{ kg m}^{-3}$), meaning that it is porous. This asteroid could indeed have been built from loose-packed rocks held together by gravity, after an impact on a larger parent body. It presents a significant topographic diversity, with boulders on rough terrains and a featureless central area of fine dust particles forming a smooth regolith in gravitational lows. Such results are of importance when considering orbital deflection techniques to be implemented if a similar asteroid was discovered on a collision course with the Earth.

Samples analyses have identified more than 1000 dust particles retrieved from Itokawa, with sizes mostly below 100 micrometers. They consist of minerals (e.g., olivine, pyroxene, plagioclase, and troilite), with water typically in low-calcium pyroxene grains, and a low content of organics (e.g., nanocrystalline graphite and disordered polyaromatic carbon). Their composition appears to be quite comparable to that of ordinary chondrites.

Definition

IUPAC, the International Union of Pure and Applied Chemistry, defines itself as “the global

organization that provides objective scientific expertise and develops the essential tools for the application and communication of chemical knowledge for the benefit of humankind and the world.” It was originally formed in 1919 in response to the need for international standardization in chemistry, including nomenclature for both inorganic and organic chemistry, standardization of atomic weights and physical constants, and tables of the properties of matter. At present, the scientific work of IUPAC is divided among eight divisions: physical and biophysical chemistry,

inorganic chemistry, organic and biomolecular chemistry, polymers, analytical chemistry, chemistry and the environment, chemistry and human health, and chemical nomenclature and structural representation. Among the activities of IUPAC is the sponsoring of IUPAC projects, which should be related to the needs of chemists in the entire world, should be relevant to the needs of mankind, and can be addressed by an international team that IUPAC can assemble. The national chemical societies of more than 50 countries are affiliated with IUPAC.

[Japan Astrobiology Consortium](#)

Definition

Nearly 4000 exoplanets have been discovered and confirmed within the last 20 years or so. The diversities of those planets have greatly expanded our view of the universe based on astronomical observations and theories. Earth sciences have also made significant progress in understanding our life-harboring planet. With these advances in astronomy and Earth sciences, as well as expansions in the fields of biology, such as extremophiles and biochemistry, the field of astrobiology is expected to grow significantly in the twenty-first century.

Based on this background, in 2012, the Tokyo Institute of Technology established the Earth-Life Science Institute (ELSI) as a World Premier International Research Center Initiative (WPI) of the Ministry of Education, Culture, Sports, Science, and Technology (MEXT) of Japan. ELSI's research mission is to elucidate how our

planet was formed and how its early environment allowed for the rise of initial life and its subsequent evolution to complexity.

In 2015, the Astrobiology Center (ABC) was established under the National Institute of Natural Sciences (NINS). Since NINS is an inter-university research institute corporation, ABC is not only advancing their research projects but also providing observational instruments to astrobiology researchers throughout the country, in addition to promoting joint research programs and funding. It also utilizes the development of astrobiology and other related fields as opportunities for international cooperation.

In 2016, both ELSI and ABC agreed to establish the Japan Astrobiology Consortium (JABC). In the future, more institutes in Japan are expected to join. JABC's mission is summarized as follows:

- To be a contact point for international astrobiology collaborations
- To be a core of domestic collaborations on astrobiology
- To promote personal exchanges for researchers and students
- To host international conferences and summer school programs on astrobiology
- To support the Japanese Astrobiology Network mailing list

Through these activities, JABC aims to expand and develop the astrobiology field in Japan.

Jack Hills (Yilgarn Craton, Western Australia)

Simon Wilde

School of Earth & Planetary Sciences, Curtin University, Perth, WA, Australia

Keywords

Continental crust · Hadean · Neoproterozoic · Oceans · Western Australia · Zircon

Definition

Jack Hills is the name of a low range of hills located in the Murchison District of Western Australia, approximately 800 km north of Perth. Since 1986, the area has been internationally known as the site of the world's oldest minerals. These are detrital zircon grains up to 4404 Ma old.

Overview

A ► [zircon](#) grain with a portion recording an age of 4404 ± 8 Ma (2σ) was extracted from a conglomerate on Eranondoo Hill in the central Jack Hills. Published in 2001 (Wilde et al. 2001), this age was ~ 130 Ma older than the previous oldest known crystal on Earth, also reported from the same site in 1986 (Compston and Pidgeon 1986). Prior to that, the oldest known zircon crystals (~ 4150 Ma) were obtained from Mt. Narryer, located ~ 60 km southwest of Jack Hills (Froude et al. 1983). A concordant U-Pb zircon age of 4463 ± 17 Ma (2σ) was obtained from another Jack Hills zircon, but this was shown to be

spurious due to mobility of radiogenic lead during a later thermal event (Ge et al. 2018).

Both Jack Hills and Mt. Narryer are located in the Narryer Terrane, which occupies an area of $\sim 30,000$ km² in the northwestern part of the Archean Yilgarn Craton of Western Australia (Spaggiari et al. 2007; Wilde and Spaggiari 2007; Kemp et al. 2018). The Jack-Hills belt is approximately 90 km long and has a sigmoidal shape. Deformation is extensive, and the contacts of the belt with adjacent deformed granites and gneisses are all sheared, so that its original disposition is obscured. The oldest known rock in Australia (3731 ± 4 Ma) is tonalitic gneiss, collected 3 km south of the Jack Hills (Nutman et al. 1991). Overall, the ages of granitoids at Jack Hills closely match those obtained from Mt. Narryer, with a spread of U-Pb dates from 3.70 to 3.30 Ga for the older components and ages of 2.65 Ga for younger monzogranites that intrude the older granitoids. The latter may locally intrude the belt itself, although the contacts are now sheared. The older granitoids record discrete age peaks at 3.75–3.65 Ga, 3.50 Ga, and at 3.30 Ga, interpreted to define major magmatic events. The oldest group of ages may record the time of extraction of the earliest tonalites from a garnet-amphibolite source. The presence of 3.3 Ga zircon rims around older cores in several sedimentary rocks indicates multiple recycling of the earliest granitoids (Cavosie et al. 2004). Importantly, evidence for 3.3 Ga-old magmatic activity appears to be restricted to the southern side of the Jack Hills belt, suggesting that the belt may lie along a major suture zone within the Narryer Terrane.

The belt itself consists of weakly metamorphosed sedimentary rocks that include ► [banded iron formation](#) (BIF), ► [chert](#), siltstone, quartzite, sandstone, and conglomerate, together with thin units of mafic and ultramafic rocks. These units have been grouped into three packages or associations (Wilde and Pidgeon 1990): (a) chemical sedimentary rocks consisting of BIF and chert, together with mafic schist (amphibolite), and minor ultramafic intrusions, that are developed along both the northern and southern margins of the belt; (b) a pelite-semipelite association characterized by quartz-biotite, quartz-chlorite, and

andalusite-bearing schists, with local mafic and ultramafic schists, which were possibly part of a turbidite sequence that now forms most of the central part of the belt; and (c) mature clastic sedimentary rocks that occur in a more restricted sequence comprising conglomerate, sandstone, quartzite, and siltstone, developed in the central and northern parts of the belt. Until 2002, all sedimentary rocks in the Jack Hills belt were considered to have been deposited in the late Mesoproterozoic to early Neoproterozoic, since no zircon younger than ~ 3.1 Ga had been recorded from the samples. However, concordant late Archean and Paleoproterozoic zircons were discovered in some of the clastic metasedimentary units with ages ranging from 2736 ± 6 to 1576 ± 22 Ma (Cavosie et al. 2004) and were also recorded in rare volcanic units interleaved with the sediments (Wilde 2010). This indicates that younger sedimentary and volcanic units are tectonically interleaved with the Archean units. It is difficult to distinguish the Archean metasedimentary rocks from the Proterozoic ones in the field, due to their lithological similarity and the effects of later deformation but a geochronological traverse through the Jack Hills belt (Wang and Wilde 2018) established that at least 12% of the rocks were Proterozoic.

The main source of ancient zircons for which Jack Hills is internationally known is the Eranondoo Hill site, commonly referred to as the W74 or Discovery site (Fig. 1), where a specific conglomerate unit yields $\sim 12\%$ zircon with ages >4 Ga, making it the richest source of Hadean material currently known on Earth. The zircon crystals are structurally complex, and a range of ages can commonly be obtained from different domains within a single crystal, attesting to their long and complex history. However, because oscillatory zoning of igneous origin defines pristine magmatic domains in many grains, the original source rocks are widely considered to be plutonic igneous rocks (Cavosie et al. 2006; Harrison et al. 2017), possibly of the **tonalite-trondhjemite-granodiorite** series (TTG) (Blichert-Toft and Albarède 2008; Nebel et al. 2013; Bell et al. 2016). **Oxygen isotope** data from such oscillatory-zoned domains in several zircon grains

Jack Hills (Yilgarn Craton, Western Australia), Fig. 1 Simon Wilde (left) and John Valley (right) standing behind the metaconglomerate of the W74 site, Jack Hills, where the oldest detrital zircons on the Earth were discovered

(including the oldest) reveal elevated values ($\delta^{18}\text{O}$ up to 7.4‰), indicating that they crystallized from the melting of preexisting supracrustal material that had undergone interaction with low-temperature liquid water (Wilde et al. 2001; Peck et al. 2001; Cavosie et al. 2005). Such zircons thus represent the earliest evidence for both **continental crust** and oceans on Earth. Furthermore, isotopic analyses reveal that some of these zircons have fractionated lithium isotope ratios that are much more variable than those recorded from fresh igneous rocks. Values of $\delta^7\text{Li}$ below -10% are present in zircons as old as 4300 Ma, suggesting that highly weathered regolith was being sampled by these early magmas (Ushikubo et al. 2009). This provides further evidence that the parent magmas of the ancient zircons incorporated material that was itself derived from the surface weathering and erosion of preexisting rock in the presence of liquid water, supporting

the hypothesis that continental crust and oceans existed at ~ 4300 Ma, within 250 Ma of the formation of Earth. This requires relatively cool temperatures at the Earth's surface between 4400 and 4325 Ma (Valley et al. 2002; Valley 2005). Additional studies of lutetium and hafnium isotopes in ancient zircons reveal that the precursor material that gave rise to the melts in which the ancient zircons crystallized had a history extending back to ~ 4.5 Ga, extremely close to the age of the Earth itself (Kemp et al. 2010). The original host-rock of the detrital Hadean zircons at Jack Hills is controversial, ranging from melts derived from a crystallized magma ocean (Kemp et al. 2010) to S-type granite (Harrison et al. 2005). It has been established from Lu-Hf systematics that they could not be derived from a single source (Wang and Wilde 2018) and that many host rocks had a felsic to intermediate composition. This ties-in with a recent study of zircons ranging in age from 4.3 Ga to 3.3 Ga that established there was no secular change in trace element values over this time span (Turner et al. 2020). Modeling of these data suggests an andesitic host, similar to those formed in modern subduction settings (Turner et al. 2020), with this lack of change from the Hadean to the Meosoarchean leading to the suggestion that plate tectonics might have operated in the Hadean. Collectively, these data point to the early development on Earth of both continents and oceans and require fairly rapid cooling following accretion, melting, and crystallization of any magma ocean that may have been present: the "Cool Early Earth" hypothesis (Valley et al. 2002).

The nature and significance of inclusions in Jack Hills zircon are also controversial, with some workers suggesting they are primary (Hopkins et al. 2008, 2010) and others maintaining they are secondary (Rasmussen et al. 2011). This has important ramifications since graphitic carbon inclusions have been interpreted to be of biogenic origin (Bell et al. 2015), whereas the association of graphitic carbon with CO_2 inclusions has alternatively been interpreted to indicate a later metamorphic origin (Menneken et al. 2017). Similarly, iron-rich inclusions in Jack Hills zircon as old as 4.2 Ga were

interpreted to provide evidence of an ancient magnetic field (Tarduno and Cottrell 2013; Bono et al. 2018) and the presence of a Hadean geodynamo, whereas Weiss et al. 2015, 2018) concluded they were the result of later re-magnetization. Whichever is correct for the above examples, it is true to say that no "inclusion" amenable to dating has proven to be older than the host zircon grain.

Basic Methodology

Virtually all the key data acquired from the Jack Hills and Mt. Narryer region that has relevance to the early Earth comes from isotopic analysis of individual zircon crystals. In the absence of any rocks on Earth older than 4.03 Ga (► [Acasta Gneisses](#) in the Northwest Territories of Canada), these zircon crystals, together with a few from other localities around the world, are all that remains of the first 500 Ma of Earth's history (Iizuka et al. 2006; Paquette et al. 2015; Miller et al. 2018; Byerly et al. 2018). With recent improvements in analytical techniques and instrumentation, it is now possible to determine in situ U-Pb, Lu-Hf, O, C, Ti, Li, and many other trace elements and isotopes with reasonable accuracy on portions of crystals only a few microns in diameter. Further advances are to be expected in the coming years.

Key Research Findings

Jack Hills in Western Australia contains the oldest known components of the Earth's crust; a portion of a zircon crystal with a $^{207}\text{Pb}/^{206}\text{Pb}$ age of 4404 ± 8 Ma (2σ) (Fig. 2). In addition, zircon crystals ~ 4.3 Ga old show elevated $\delta^{18}\text{O}$ values and strongly negative $\delta^7\text{Li}$ values, indicating they grew during melting of a protolith that evolved through weathering and interaction with liquid water at the Earth's surface, possibly in a CO_2 -rich atmosphere. Lu-Hf isotope data from the zircons suggest the earliest crust may have formed as early as ~ 4.5 Ga, close to the age of the Earth itself (Harrison et al. 2005; Kemp et al. 2010).

Australia), Fig. 2 Photo of the oldest zircon at site W74, Jack Hills, Yilgarn Craton (Western Australia). The ancient crystal was imaged in cathodoluminescence prior to the second analytical session that identified the 4.404 Ga portion (in red). (Photo Simon Wilde)

Applications

The Jack Hills zircons constitute the main database for study of the first 500 Ma of Earth's history (► [Hadean](#); ► [Earth, Formation and Early Evolution](#)). As such, they represent a unique inventory and, when other areas containing Hadean zircons are discovered, they provide the standard used for comparison.

Future Directions

Further work at Jack Hills can provide answers to the following problems: (1) the exact nature of the host rocks of the ancient zircon crystals, (2) whether any remnants of those rocks are still present in the area, (3) the veracity or otherwise of a Hadean magnetic field, and (4) if there are any true inclusions older than the Hadean zircon hosts.

Definition

Jarosite is a ferric hydrous sulfate mineral with the chemical formula of $\text{KFe}_3(\text{SO}_4)_2(\text{OH})_6$ that has a trigonal crystal system and belongs to the group of ► [alunite](#). This ochre-yellow or brown mineral forms under aqueous, acidic, and oxidizing conditions through, e.g., ► [weathering](#) of volcanic rocks in the presence of acidic, sulfur-rich fluids or by oxidation of sulfide minerals in acid drainage environments.

The Mössbauer spectrometer on Mars Exploration Rover Opportunity has detected up to 10 wt% of jarosite in the sedimentary rocks at *Meridianum Planum* (Klingelhöfer et al. [2004](#)). This discovery was insofar a breakthrough, as it constrained the chemistry of the aqueous paleoenvironment with respect to its redox potential (being oxidizing) and its pH (being acidic). Furthermore, it is known that jarosite rapidly decomposes under humid conditions over geologic time, which suggests that the aqueous period of jarosite formation was followed by predominantly dry conditions (Elwood Madden et al. [2004](#)).

Definition

On October 1, 2003, the Institute of Space and Astronautical Science (ISAS), the National Aerospace Laboratory of Japan (NAL), and the

National Space Development Agency of Japan (NASDA) were merged into one independent administrative institution to be able to perform all their activities in the aerospace field as one organization, from basic research and development to utilization. The independent administrative institution is the Japan Aerospace Exploration Agency (JAXA).

This administration manages 17 facilities across Japan as well as overseas offices. From the Tanegashima Space Center, national rockets H-II are regularly launched. Through JAXA, Japan is a major partner of the international space station and contributes with the KIBO scientific module. The H-II Transfer Vehicle (HTV) is JAXA's unmanned cargo transfer spacecraft that delivers supplies to the International Space Station (ISS).

The first Japanese citizen to fly in space was a journalist, Toyohiro Akiyama, who flew on the Soviet Soyuz TM-11 in December 1990, while the expenses (around 14 million USD) were paid by a broad-casting company. JAXA has ten professional astronauts of staff, who are supporting experiments onboard the ISS.

JAXA's missions with relevance to astrobiology include those to Halley's comet (Suisei and Sakigake), to the asteroid 25143 Itokawa ("Hayabusa") which returned some grains of surface material to the Earth in 2010, and more recently Hayabusa2, which sampled material from the asteroid 162173 Ryugu. Ryugu is a more primitive-type asteroid than Itokawa and presumably contains organic material. Hayabusa2 successfully returned its samples to Earth in December 2020. The mission of Hayabusa2 has been extended to at least 2031, when it will hopefully rendezvous with asteroid 1998 KY₂₆.

Jeans Criterion

Daniele Galli

INAF Osservatorio Astrofisico di Arcetri, Largo
E. Fermi 5, Italy

Keywords

Gravitational instability · Gravitational collapse · Free-fall timescale · Fragmentation · Interstellar cloud · Protoplanetary disk

Definition

The Jeans criterion describes the condition for the onset of *gravitational instability* in a medium of density ρ and temperature T .

Perturbations of size larger than the Jeans length $\lambda_J = \pi c_s / (G\rho)^{1/2}$, where $c_s = (k_B T/m)^{1/2}$ is the sound speed, are unstable and collapse under their own self-gravity. The criterion is applicable to interstellar clouds supported by gas pressure against gravity.

History

The criterion was first derived in 1902 by the British physicist James H. Jeans (1877–1946). See Jeans (1902) and Jeans (1928).

Overview

The Jeans criterion is central to the process of star formation. Consider the simple case of an *interstellar cloud* supported against its own gravity by gas pressure alone. If the cloud is sufficiently massive, gravitational attraction can overwhelm the support provided by gas pressure. The cloud then becomes gravitationally unstable, and can collapse to form stars. The Jeans criterion gives the value of the maximum mass (or size) of a cloud in equilibrium under the balance of gravity and pressure. It can also be applied to the formation of giant planets in a *protoplanetary disk*.

Equivalent formulations of the Jeans criterion can be derived from the *virial theorem*, or from the stability analysis of spherical self-gravitating equilibrium models. The simplest derivation is from the analysis of the propagation of small-amplitude waves in a homogeneous isothermal gas with density ρ and temperature T . A perturbative analysis shows that density perturbations of small wavelength propagate like sound waves with speed $c_s = (k_B T/m)^{1/2}$. However, because of the gravitational attraction, the velocity of wave propagation decreases with increasing wavelength. Above a critical wavelength $\lambda_J = \pi c_s / (G\rho)^{1/2}$, called the Jeans length, wave propagation is not possible: the amplitude of disturbances extending over scales larger than λ_J increases exponentially with time. This is the *gravitational instability*. The mass M_J contained inside a radius equal to λ_J is called the Jeans mass, and is the maximum mass that can be in equilibrium under a balance of gravity and pressure.

The Jeans criterion is frequently adopted to estimate whether a molecular cloud (or a part of it) is gravitationally stable or not, and, in the latter case, to estimate the typical size of fragments that can be formed as a consequence of the cloud's collapse. Very often, since giant molecular clouds are supported by turbulent motions rather than by gas pressure, the sound speed c_s in the expressions for the Jeans length and Jeans mass, is replaced by the average turbulent speed, a procedure justified on the basis of the *virial theorem*. However, the inclusion of the effects of turbulence, rotation and magnetic fields on the gravitational instability requires a more detailed analysis.

It must be stressed that the Jeans criterion provides a necessary, but not sufficient, condition for cloud collapse. If the gravitational energy released by the collapse is not radiated away but converted into thermal energy, the temperature (and therefore the pressure) of the cloud rises, halting the collapse. Molecular clouds can efficiently radiate the excess energy, maintaining an approximate constant temperature during the initial phase of collapse. As long as the cloud's pressure is overwhelmed by gravity, the collapse occurs on a *free-fall time* $t_{\text{ff}} = \lambda_J / c_s = \pi / (G\rho)^{1/2}$. It must also be noted that the Jeans length in a collapsing cloud

becomes smaller as the cloud density increases. This allows parts of the clouds (e.g., density inhomogeneities) to become in turn gravitationally unstable, leading to cloud *fragmentation*. Suggested readings: Binney and Tremaine (2008), Stahler and Palla (2004).

Definition

Juno is one of the larger main-belt asteroids with an estimated average diameter of about 240 km. It is also one of the largest stony (S-type) asteroids. With an albedo of 0.24 Juno is at the bright end of a typical S-type asteroid. Juno orbits the Sun at an average distance of 2.67 AU with an orbital period of 4.36 years. The orbit is moderately inclined but has an eccentricity of 0.255 which is higher than that of Pluto. Juno has a rotation period of 7.21 h.

Absorption spectra show a surface composed of iron-bearing silicates and reveal a region of relatively low apparent brightness. This feature can be interpreted as large impact crater >100 km in diameter or a fresh ejecta blanket due to a geologically young impact.

History

Juno was discovered by German astronomer Karl L. Harding in 1804. Juno was the third asteroid discovered.

Giant planets

Definition

Among the Giant planets, Jupiter is the most massive and also the closest to the Sun; it orbits at 5.2 AU from the Sun. Its mass is 318 times the terrestrial mass and its diameter is 11 times the terrestrial one, which corresponds to a density of 1.31 g/cm^3 . As the other giant planets, Jupiter was formed in the outer solar system by the accretion of a core with a rock/ice composition followed by the collapse of the surrounding nebula, mostly composed of hydrogen and helium but also containing more refractory elements. It is widely

agreed that Jupiter formed rapidly, within a few million years, in the outer solar system beyond the snowline which marks the condensation of ices in the protosolar disk. Jupiter has a tenuous ring system and 69 satellites (as of 2018), regular and irregular ones. The regular satellites were formed in the equatorial plane of the planet after the collapse of the surrounding subnebula. They include the four Galilean satellites (Io, Europa, Ganymede, and Callisto) discovered by Galileo Galilei in 1610. The irregular satellites are probably captured distant asteroids.

Overview

Early Observations

As one of the brightest objects in the sky, Jupiter has been known since Antiquity. Its astronomical observation started in 1610 with the first observations by Galileo Galilei. A few decades after the discovery of the Galilean satellites, the band and zone structure of Jupiter, induced by its fast rotation period (9 h 55 min), was observed. In 1664, Robert Hooke identified the Great Red Spot (GRS) which was studied in detail by Giovanni Domenico Cassini in the following years. Since then, the planet has been continuously monitored, showing, in particular, the stability of the GRS over more than three centuries.

Atmospheric compounds were first identified by spectroscopy in the twentieth century: CH₄ and NH₃, minor components but strong spectroscopic absorbers, were identified by Wildt in 1932. Hydrogen, the dominant species but less active spectroscopically, was expected to be present on a theoretical basis but was not detected until 1961. Since the 1970s, the development of infrared spectroscopy has led to the detection of a long list of minor constituents (PH₃, GeH₄, SiH₃, CO, C₂H₂, C₂H₆, ...). It must be noted that most of these species have been detected from ground-based observations. In 1994, the collision of the Shoemaker-Levy comet with Jupiter provided astronomers with a unique opportunity to study in real time the response of an atmosphere to a major meteoritic impact. Many new molecules

were formed by shock chemistry (H₂O, CO, CS, OCS, HCN, ...), some of them remaining detectable in the following years.

Another major result of the ground-based exploration of Jupiter was the discovery, in the 1950s, of a strong radio-emission, both in the decimeter and decameter range. This nonthermal emission was interpreted as the signature of a magnetic field, a result which was later confirmed by space exploration.

The Space Exploration of Jupiter

Jupiter and Saturn were first encountered by the two spacecraft Pioneer 10 and Pioneer 11, in 1973 and 1974, respectively. They sent the first high-resolution images of the atmospheric structure and the first in situ exploration of the Jovian magnetosphere. This first step was followed by the very successful Voyager missions, which consisted of two identical spacecraft which flew by the four giant planets between 1979 and 1989. Jupiter was visited by Voyager 1 and Voyager 2 in 1979. Among the many discoveries of the Voyager mission, one should quote the unexpected complexity of the Jovian cloud structure, the evidence for a tenuous ring system around the planet, the evidence for active volcanism on Io, and the surface diversity of the other Galilean satellites. Several other small satellites were also discovered.

After these flybys, a more ambitious mission, including an orbiter and an atmospheric descent probe, was dedicated to the exploration of the Jovian system. In 1995, NASA's Galileo orbiter approached the planet and a probe was sent into its atmosphere. The probe transmitted data in the deep troposphere down to a pressure level of 22 bars. The orbiter monitored the planet's atmospheric and cloud structure as well as the Galilean satellites until 2003. In 2000, Jupiter was also observed by the Cassini spacecraft on its way to the Saturn system, and some combined measurements of the atmosphere and the magnetosphere by both spacecraft were successfully accomplished.

In August 2011, the JUNO spacecraft was launched by NASA with the main objective of probing Jupiter's interior and measuring its

gravity and magnetic fields, in order to better understand its formation scenario. The spacecraft reached Jupiter in 2016 and is performing polar orbits around the planet, thus bringing new information on the planet's atmosphere, internal structure, and magnetosphere.

For the future, a couple of missions are already foreseen by the space agencies, such as NASA's Europa Clipper which will investigate the moon after a launch between 2022 and 2025, but more importantly for Jupiter ESA selected in 2012 an even more ambitious mission, JUICE (JUPiter ICy moon Explorer), to be launched in 2022 for an arrival in 2030. The spacecraft will perform several maneuvers around Jupiter and its Galilean satellites, including two flybys of Europa, and will enter orbit around Ganymede in 2033. In the course of its 3-year nominal mission, JUICE will study the atmosphere, the magnetosphere and all the coupling processes in which Jupiter is involved within its system. In particular, JUICE will provide a global characterization of the Jovian atmosphere, from the clouds of its turbulent, convective troposphere, all the way through the middle atmosphere to the thermosphere. The results will bring us a better understanding of the dynamics, circulation, composition, chemistry, vertical structure, and coupling therein. This will be achieved by a combination of high inclination trajectories and broad coverage at different wavelengths (Fig. 1).

Dynamical Atmospheric Structure

The main cloud features of Jupiter – Great Red Spot, zones (whitish) and belts (brownish) – are known since the seventeenth century. The zone and belt structure can be interpreted, to first order, as a Hadley circulation with multiple cells generated by the fast rotation of Jupiter. Zones are regions of ascending motion and belts are regions of subsidence. Measurements by the Galileo probe, in 1995, confirmed this convective pattern, but they also showed that the present circulation is much more complex than this simple scheme.

The Coriolis forces induce zonal winds of opposite direction, north and south of each zone, generating multiple time-variable eddies. The biggest structure is the Great Red Spot in the southern

Jupiter, Fig. 1 The planet Jupiter as observed by the Cassini spacecraft in 2000. The Great Red Spot is clearly visible in the southern hemisphere, as well as the zone (whitish) and belt (brownish) structure all over the planet demonstrating the existence of a dynamical atmosphere. (Source: © NASA)

hemisphere. Its size is about 10,000–14,000 km in the north–south axis and 24,000–40,000 km in the east–west axis. The GRS is believed to be a giant anticyclonic structure; however, its stability over several centuries is not yet completely understood. The composition of the GRS, in particular its red color, is still an open question; it might be due to sulfur or phosphorus compounds, but their exact chemical composition remains unknown.

The Juno mission, in polar orbit around Jupiter since 2016, has revealed the unexpected complexity of atmospheric dynamics near the polar regions. The fast rotation of the planet and the strong Coriolis forces are responsible for the alternating zonal flows which have been observed for

long at low and mid-latitudes, but also to circumpolar cyclones near the poles. Surprisingly, the structures of these cyclones are not the same around the two poles, with eight circumpolar cyclones around the north pole and five around the south pole. These structures are also different from the persistent hexagonal features of Saturn's north pole. The reasons for the differences in these dynamical systems, as well as their stability, are still unknown. In addition, Juno instruments found that the atmospheric winds on Jupiter are long lasting and run deep into the atmosphere which has implications on our understanding of Jupiter's interior structure, core mass and, subsequently its origin. In June 2018, Juno made significant discoveries on lightning on Jupiter and the ways in which it is analogous to Earth's lightning, while the two types of lightning are somehow polar opposites. These findings significantly improved our understanding of the composition, circulation, and energy flows on Jupiter although the current distribution of lightning (mostly at the north pole) is not completely understood.

Atmospheric Composition and Structure

As all giant planets, the thermal vertical profile of Jupiter is characterized by a troposphere where the temperature decreases adiabatically with altitude and a tropopause where the temperature is minimum ($T = 110$ K at $P = 100$ Mbar). Above the tropopause, the temperature increases again with the altitude, due to the absorption of the solar infrared flux by methane and aerosols. At higher altitudes, other mechanisms contribute to a strong heating (planetary waves, high-energy particles).

As hydrogen is the main atmospheric component, most of the other species are in a reduced state. A first group consists in tropospheric compounds: CH_4 , NH_3 , PH_3 , GeH_4 , AsH_3 , CO , and H_2O . H_2S , not detected by spectroscopy, was identified by the mass spectrometer of the Galileo probe. Most of these species condense at the level of the tropopause, where the temperature is minimum, the two exceptions being CH_4 and CO . A second group contains the hydrocarbons produced by the photolysis of methane in the Jovian stratosphere (C_2H_2 , C_2H_4 , C_2H_6 , CH_3 , C_3H_8 , C_6H_6 ...). A third group includes oxides detected

in the Jovian stratosphere (H_2O , CO , CO_2) which have an external origin; indeed, if water came from the interior it would be trapped as ice at the tropopause. Following recent observations by the Herschel satellite, the origin of water seems to be the collision of comet Shoemaker-Levy 9 with Jupiter in 1994.

The cloud structure of Jupiter can be inferred from models of thermochemical equilibrium. At a pressure of about 0.5 bar, ammonia clouds are expected; they are believed to be responsible for the white color of the Jovian zones. At deeper tropospheric levels (about 2 bars), models predict clouds of nitrogen hyposulfide NH_4SH , and at a pressure of a few bars, water clouds should be present. The presence of water clouds has been demonstrated with the Near Infrared Mapping Spectrometer of Galileo; however, the spatial distribution of the Jovian cloud structure appears to be much more complex than expected from the models. There is an active convective circulation between zones and belts, as previously anticipated, with zones being upwelling regions, rich in clouds, and belts being regions of subsidence. However, the Galileo observations have shown that even within the belts, there are cloud-free, specific holes which are downwelling regions. In these regions, the radiation comes from deeper, warmer layers, hence their being called "hot spots." The Galileo probe entered one of these regions, free of clouds and very dry. The H_2O cloud was absent there, but the very low measured water content is not representative of the whole planet. Apart from oxygen, many other elements were successfully measured by the mass spectrometer of the Galileo probe.

Elemental and Abundance Ratios in Jupiter

The Galileo mass spectrometry measurements of the Jupiter atmosphere showed a general enrichment in all heavy elements with respect to hydrogen, as compared to the protosolar value. This enrichment factor, first estimated to 3 ± 1 , is now considered as being 4 ± 2 after revision of the solar abundances. This result provided a decisive support for the core accretion model for giant planet formation. According to this scenario, giant planets result of the accretion of a solid core

(mostly made of the rock and ice components) of about 10–12 terrestrial masses; then the gravity field of this accreted core was sufficient to induce the collapse of the surrounding nebula mainly composed of hydrogen and helium. After the collapse phase and the vaporization of the ices of the core, the relative abundances of heavy elements (C, N, O, S, and noble gases) must have been enriched with respect to their protosolar abundances. It can be shown that, if all elements were equally trapped in ices, an enrichment factor of 4 would be expected for Jupiter, which is in perfect agreement with the Galileo measurements. However, the general enrichment of Jupiter's planetesimals raises another question: some species, like N and Ar, cannot be trapped in ices unless their temperature is very low (<40 K). Their presence in Jupiter indicates that Jupiter's planetesimals accreted at a temperature much lower than that simply deduced from Sun–Jupiter distance. The origin of Jupiter's planetesimals still remains an open question.

The JUNO mission has been designed to help bring some new answers to this question. In particular, a determination of the O/H ratio in the deep interior of the planet was part of the objectives of the mission; this key measurement, as mentioned above, could not be performed by the Galileo probe. However, the first results of the JUNO Microwave Radiometry experiment, designed to probe the deep atmosphere of Jupiter down to a pressure of a few hundred bars, has shown that the dynamics of the deep atmosphere are by far more complex than anticipated. In particular, the ammonia mixing ratio below the H_2O and NH_4SH clouds is not constant until it reaches pressure levels higher than 60 bars; this unexpected result is likely to make more difficult the retrieval of the water content.

Internal Structure

We do not have direct measurements of Jupiter's internal structure. The only known parameters are its diameter, mass, density, and gravitational moments. The Voyager infrared spectrometer IRIS showed that Jupiter radiates more heat than it receives from the Sun (1.67 times the absorbed solar energy). The origin of this internal energy

would be the cooling of the planet, still in a slow contracting phase after the initial accreting phase. Helium condensation in Jupiter's interior, within the hydrogen metallic ocean, might also contribute to the internal energy.

Based on these constraints, theoretical models of Jupiter's internal structure have been proposed. It would consist in a rocky/icy core having a temperature of about 23,000 K, while the pressure would range from 50 to 100 Mbar or 5 to 10 TPa. This core would be surrounded by a convective ocean of metallic hydrogen and helium, above which, at about 0.8 Jovian radii, a layer of mostly molecular hydrogen and helium is expected to extend up to the observable layers of the atmosphere. However, the gravimetry measurements of the Juno mission have brought new information and also new questions about the internal structure of Jupiter. The measurement of Jupiter's gravitational harmonics has shown that Jupiter's gravity field is north–south asymmetric; the zonal flow observed at the cloud level actually persists down to a depth of about 3000 km below the cloud top. At this level, the electric conductivity would become sufficient for the differential rotation to be suppressed by magnetic drag, and closer to the center, the deep interior would rotate nearly as a rigid body. More results are expected to come as the JUNO mission continues its exploration around Jupiter.

The Jovian Magnetosphere

The large magnetosphere of Jupiter, first identified by the Jovian synchrotron radiation and later explored by spacecraft, can be explained by several factors: the great size of the planet, its fast rotation, and the presence of a liquid metallic interior. The Jovian magnetic field is generated by a dynamo effect within the ocean of metallic hydrogen and/or in electrically conductive sublayers of the molecular layer above. The dipole moment is tilted by 10° with respect to the rotation axis of the planet. This magnetic field is 14 times stronger than the Earth's.

As Jupiter is five times more distant to the Sun than the Earth and with a substantially stronger magnetic field, its magnetosphere is considerably more extended than the terrestrial one. Still, its structure shows strong analogies with the Earth's

magnetosphere. A shockwave, a magnetopause, and a magnetosheath are present in the sunward direction. The main difference is the interaction of the Jovian magnetosphere with Io (and to a lesser extent with Europa) whose orbit crosses the Jovian magnetosphere.

The magnetic field of Jupiter has also been explored by the JUNO mission. The first results of its magnetometer show that, near the cloud top, Jupiter's magnetic field is different from the expected models; this might imply that the region where the dynamo is generated could be located not very far beneath the surface, possibly (at least in part) in the molecular hydrogen layer, above the region where hydrogen is expected to be in metallic form.

The biggest planet of our solar system is the archetype of giant exoplanets. It is also where almost all the matter which is not in the sun has been stored. This makes it one of the most valuable objects to explore for understanding the origins and the bulk composition of our solar system but also of other planetary systems. Furthermore, it is our best example of connectivity between the different atmospheric layers, the atmosphere and interior, and the atmosphere and external environment. ESA's JUICE mission will considerably enhance our understanding of Jupiter in the 2030s.

JUICE

Definition

The JUICE (JUPiter ICy moon Explorer) mission, selected in May 2012 to be the first large mission within the ESA's Cosmic Vision Program 2015–2025, will provide the most comprehensive exploration to date of the Jovian system in all its complexity, with particular emphasis on Ganymede as a planetary body and potential habitat. Investigations of the neighboring moons, Europa and Callisto, will complete a comparative picture of the environmental conditions on the Galilean moons and their potential habitability. The JUICE mission has been formulated with consultation and strong support from the international planetary science community, and it will have broad appeal across a range of different disciplines including geologists, astrobiologists, and magnetospheric and atmospheric scientists. Due to launch in April 2023, it will arrive at Jupiter in July 2031. The mission is planned to end in September 2035.

History

In 1995, the Galileo spacecraft arrived at Jupiter to conduct the first detailed orbital exploration of the

Jovian system in the footsteps of previous flyby missions (Pioneer 10–11, Voyager 1–2, and Ulysses). Despite its limitations, Galileo made a plethora of new discoveries in the Jovian system, especially as concerns the four Galilean satellites, each of which was revealed as a unique world and a fascinating destination for further in-depth exploration. Most importantly, Galileo discovered strong evidence for the existence of subsurface oceans hidden beneath the icy crusts of Europa, Ganymede, and Callisto, leading to the emergence of a new habitability paradigm that considers the icy satellites as potentially habitable. If extrasolar planetary systems share a common planetary architecture to our own solar system, then icy satellites of gas giants, having a subsurface liquid water ocean, could be the most common habitats in the Universe, probably much more abundant than earthlike environments, which require highly specialized conditions that permit surface oceans.

The detailed JUICE characterization of the wider Jovian system will extend the Juno mission's focused study of Jupiter's interior and inner magnetosphere that started in 2016 and will be the next logical step in our exploration of the outer solar system after Cassini's exploration of the Saturn system.

Overview

The overarching theme for JUICE is the emergence of habitable worlds around gas giants. Within our Solar System, we know of one body that has experienced the emergence of life: On Earth, living organisms have developed and proliferated even under the most extreme of environmental conditions. Is the origin of life unique to our planet or could it occur elsewhere in our Solar System or beyond? To answer this question, even though the mechanisms by which life originated on Earth are not yet clearly understood, one can assume that the necessary conditions involve the simultaneous presence of organic compounds, trace elements, water, energy sources, and a relative stability of the environment over time. JUICE will address the question: Are there current habitats elsewhere in the Solar System with the

necessary conditions (water, biological essential elements, energy, and stability) to sustain life? The spatial extent and evolution of habitable zones within the Solar System are critical elements in the development and sustainment of life as well as in addressing the question of whether life developed on Earth alone or whether it could have developed in other Solar System environments and was then imported to Earth. JUICE's objectives are listed in Table 1.

The focus of JUICE is to characterize the conditions that may have led to the emergence of habitable environments among the Jovian icy satellites, with special emphasis on the three ocean-bearing worlds, Ganymede, Europa, and Callisto. Ganymede is identified for detailed investigation not only since it provides a natural laboratory for analysis of the nature, evolution, and potential habitability of icy worlds in general, but also because of the role it plays within the system of Galilean satellites, and its unique magnetic and plasma interactions with the surrounding Jovian environment. JUICE will determine the characteristics of liquid water oceans below the icy surfaces of the moons, mainly with its magnetometer, laser altimeter, and radio-science experiments. This will lead to an understanding of the possible sources and cycling of chemical and thermal energy, allow investigation of the evolution and chemical composition of the surfaces and of the subsurface oceans, and enable an evaluation of the processes that have affected the satellites and their environments through time. The study of the diversity of the satellite system will be enhanced with additional information gathered remotely on Io and the smaller moons. The mission will also characterize the diversity of processes in the Jupiter system that may be required in order to provide a stable environment at Ganymede, Europa, and Callisto on geologic timescales, including gravitational coupling between the Galilean satellites and their long-term tidal influence on the system as a whole. The advanced instrumentation carried by JUICE (Table 2) will also permit extensive new studies of Jupiter's atmosphere (its structure, dynamics, and composition) and magnetosphere (three-dimensional properties of the

Jupiter Icy Moon Explorer Mission, Table 1 Science goals and objectives of JUICE

Exploration of the habitable zone: Ganymede, Europa, and Callisto	
Characterize Ganymede as a planetary object and possible habitat	Characterize the extent of the ocean and its relation to the deeper interior
	Characterize the ice shell
	Determine global composition, distribution, and evolution of surface materials
	Understand the formation of surface features and search for past and present activity
	Characterize the local environment and its interaction with the Jovian magnetosphere
Explore Europa’s recently active zones	Determine the composition of the nonice material, especially as related to habitability
	Look for liquid water under the most active sites
	Study the recently active processes
Study Callisto as a remnant of the early Jovian system	Characterize the outer shells, including the ocean
	Determine the composition of the nonice material
	Study the past activity
Explore the Jupiter system as an archetype for gas giants	
Characterize the Jovian atmosphere	Characterize the atmospheric dynamics and circulation
	Characterize the atmospheric composition and chemistry
	Characterize the atmospheric vertical structure
Explore the Jovian magneto sphere	Characterize the magnetosphere as a fast magnetic rotator
	Characterize the magnetosphere as a giant accelerator
	Understand the moons as sources and sinks of magnetospheric plasma
Study the Jovian satellite and ring systems	Study Io’s activity and surface composition
	Study the main characteristics of rings and small satellites

magnetodisc and coupling processes), and their interaction with the Galilean satellites will further enhance our understanding of the evolution and dynamics of the Jovian system. The long-term Jovian magnetospheric and atmospheric science will push significantly beyond the capabilities of previous missions like Galileo and directly complement the results of the short-lived Juno mission.

Basic Methodology

JUICE mission scenario and spacecraft. Following a launch with Ariane 5, JUICE will use an Earth/Moon-Earth-Venus-Earth-Earth gravity assist strategy to reach Jupiter. The cruise maneuvers are small, so that the mass reaching Jupiter is large. The nominal launch date is in April 2023, with an arrival at Jupiter in July 2031. The backup launch is in August/September 2023. After

insertion into Jupiter orbit, JUICE will use multiple gravity assists via flybys of the Galilean satellites to shape a comprehensive orbital tour over ~3.5 years. After reducing the orbit period with Ganymede flybys, this tour will implement two close Europa flybys, then a series of Callisto flybys so as to reach an inclination of 33° with respect to the equatorial plane of Jupiter. A dedicated series of Callisto then Ganymede gravity assists will make it possible to approach Ganymede at a low velocity. During the tour, Jupiter’s magnetosphere and atmosphere will be continuously monitored. At the end of the tour, JUICE will be set in a polar orbit around Ganymede, becoming the first spacecraft in history to enter orbit around an icy satellite in the outer solar system. This dedicated orbital phase will provide a comprehensive survey of the Solar System’s largest planetary satellite. The lowest orbit will be at 500 km in the baseline scenario and could reach 200 km depending on the propellant used

Jupiter Icy Moon Explorer Mission, Table 2 JUICE set of instruments with their main characteristics

Instrument acronym	Short description
JANUS	J ovis, A morum ac N atorum U ndique S crutator An optical camera to study moon geology, and to perform mapping of the clouds on Jupiter. JANUS will have 13 filters covering the range 350–1050 nm, a 1.3 degree field of view, and spatial resolution up to 2.4 m on Ganymede and about 15 km at Jupiter
MAJIS	M oons A nd J upiter I maging S pectrometer A hyperspectral imaging spectrometer for observing tropospheric cloud features and minor species on Jupiter and for the characterization of ices and minerals on the surfaces of icy moons. MAJIS will cover the 0.4 to 5.7 microns range, with spectral resolution of 3–7 nm. The spatial resolution will be up to 60 m on Ganymede and about 130 km on Jupiter
UVS	U V Imaging S pectrograph A UV spectrometer to characterize the composition and dynamics of the exospheres of the icy moons, to study the Jovian aurorae, and to investigate the composition and structure of the upper atmosphere. UVS will cover the wavelength range 55–210 nm with spectral resolution of <0.6 nm. Spatial resolution will reach 0.5 km at Ganymede and up to 500 km at Jupiter
SWI	S ubmillimeter W ave I nstrument A submillimeter wave instrument to investigate the temperature structure, composition, and dynamics of Jupiter's stratosphere and troposphere, and the exospheres and surfaces of the icy moons. SWI is a heterodyne spectrometer using a 30 cm antenna and working in two spectral ranges 1080–1275 GHz and 530–625 GHz with spectral resolving power of $\sim 10^7$
GALA	G anymede L aser A ltimeter A laser altimeter for studying the tidal deformation of Ganymede and the morphology and topography of the surfaces of the icy moons. GALA will have a 20 m spot size at 200 km and 0.1 m vertical resolution
RIME	R adar for I cy M oons E xploration An ice-penetrating radar to study the subsurface structure of the icy moons down to 9 km depth with vertical resolution of up to 50 m in ice. RIME will work at a central frequency of 9 MHz and will use a 16 m dipole antenna
J-MAG	J UICE M AGnetometer A magnetometer to characterize the Jovian magnetic field, its interaction with the internal magnetic field of Ganymede, and to study subsurface oceans of the icy moons. J-MAG will use fluxgates sensors and a scalar magnetometer for absolute calibration mounted on a boom
PEP	P article E nvironment P ackage A package of sensors to characterize the plasma environment in the Jovian system. PEP will measure density and fluxes of positive and negative ions, electrons, exospheric neutral gas, thermal plasma, and energetic neutral atoms in the energy range from <0.001 eV to >1 MeV with full angular coverage. The composition of the moons' exospheres will be measured with a resolving power of more than 1000
RPWI	R adio & P lasma W ave I nvestigation A radio and plasma wave instrument to characterize the radio emission and plasma environment of Jupiter and its icy moons. It will use Langmuir probes to measure DC electric field vectors up to a frequency of 1.6 MHz and to characterize thermal plasma and medium- and high-frequency receivers, and dipole antennas and magnetometers to measure electric and magnetic fields in radio emission in the frequency range 80 kHz–45 MHz
3GM	G ravity & G eophysics of J upiter and G alilean M oons GM is a radio science package comprising a Ka transponder and an ultrastable oscillator to study the gravity field and the extent of internal oceans on the icy moons, and to investigate the structure of the neutral atmospheres and ionospheres of Jupiter (0.1–800 mbar) and its moons
PRIDE	P lanetary R adio interfere & D oppler E xperiment PRIDE will use the telecommunication system of the spacecraft and ground based very long baseline interferometry to perform precise measurements of the s/c position and velocity

during the mission and on spacecraft health. The current end of mission scenario involves spacecraft disposition on Ganymede.

The spacecraft uses a conventional bipropellant propulsion system. The basic design for the spacecraft is very similar to that of previous large flight systems such as Cassini, Mars Reconnaissance Orbiter, and Rosetta. JUICE will be the second Jovian mission using solar arrays as the power source, following Juno. JUICE's trajectory will remain outside of Jupiter's inner radiation belts to provide a long-lived, stable, and versatile platform to accomplish the broad range of science objectives.

JUICE Payload (Table 2). The JUICE spacecraft will carry a highly capable suite of ten state-of-the-art scientific instruments. The remote sensing package includes spectro-imaging capabilities from the ultraviolet to the near-infrared, an imaging system, and a submillimeter wave instrument. The geophysical package includes laser altimetry and radar sounding for exploring the surface and subsurface of the moons. The radio science instrument complements the remote sensing package (to enable probing of the Jovian/satellite atmospheres) and the geophysics package (enabling estimation of gravity fields). The in situ package includes a magnetometer, a radio, and plasma wave instrument as well as a particle package. This payload suit will be supported by an experiment using ground-based very-long-baseline interferometry (VLBI). Since the selection of the payload in 2013, a thorough effort has been made to ensure that the numerous scientific objectives related to the study of the emergence of habitable worlds in the Jovian system (internal structure, geology, composition, and tenuous exospheres of the icy moons and composition and dynamics of the giant atmosphere, magnetospheres, and plasma environment) can be achieved with the selected payload, with important benefits of synergies between individual measurements.

Future Directions

The European Space Agency has selected in June 2021 the scientific themes for its science program

for the timeframe 2035–2050. One of the top priorities will be the investigation of the habitability potential of worlds in our Solar System, in particular the moons of Jupiter or Saturn. Building on the legacy of the international Cassini-Huygens mission to Saturn and ESA's upcoming Jupiter Icy Moons Explorer, a future outer Solar System mission with advanced instrumentation would focus on the study of the connection of ocean-bearing moon interiors with their near-surface environments, also attempting to search for possible biosignatures.

Definition

The James Webb Space Telescope (JWST) is an infrared space telescope project led by ► [NASA](#) with major contributions of the European Space Agency (ESA), the Canadian Space Agency (CSA) and space agencies from other nations. The development lasted two decades. The 6250 kg spacecraft has been launched on December 25, 2021, to be placed around the Sun-Earth L2 Lagrange point. The telescope is composed of a segmented primary mirror with a diameter of about 6.5 m. The focal point is equipped with four major instruments which are working in the Near and Mid Infrared wavelengths. They combine various functions of taking picture (cameras), analyzing the light (spectrometer), and blocking the starlight (coronagraph).

History

In 1989, while the Hubble space telescope was awaiting to be launched, scientists and engineers

gathered at the Space Telescope Science Institute to shape the Next Generation Space telescope. This workshop outlined that the typical lead time to develop such a major project is 25 years. The basic trade-off was between a 10 m telescope in high Earth orbit or a 16 m telescope on the moon (Bely 1989). Finally in 1996 a group of scientists, HST and beyond Committee, gathered by the Association of Universities for Research in Astronomy has delivered the report defining the main requirements of the Next Generation Space telescope. The committee used widely the material which was provided by three independent study teams. The telescope must have a mirror larger than 4 m, and the orbit could be either at L2 or a 1 to 3 AU ellipse, to reach in any case a low temperature (70 K or less) allowing infrared observations in the 1–5 μm wavelength. In this report it was assumed that the construction could be achieved for 2005 and for a cost less than \$700 million (US cost). Finally in 2002 the industrial teams and the science teams for the building of the telescope have been selected while the international cooperation has been organized. Scientists, engineers, and professionals from up to 14 countries contributed throughout the two decades of development. The European and Canadian contributions to the instruments and the launch have been finalized.

Overview

The James Webb Space Telescope was launched from Kourou (French Guyana) December 25, 2021, with an Ariane5 rocket. The secondary mirror and the primary segmented mirror have been successfully deployed as well as the large five layer sunshield which unfurled smoothly (Fig. 1). From its working position, at the L2 Lagrange point, the telescope will always face the night side of the Earth and the Moon. JWST can only point at roughly half of the sky at a given moment. While orbiting the sun at the same pace than the Earth, it will point at any point in the sky on the course of one year. Each 18 segments of the primary mirror can be adjusted with 6 degrees of

JWST, Fig. 1 An overall view of the telescope while the integration teams carefully guide Webb's suspended telescope sections into place just prior to integration. (Image credit: NASA/Chris Gunn)

freedom to achieve a “perfect alignment.” This is performed with the NIRC*am* instrument through a process known as a wavefront sensing and control. While traveling to the L2 Lagrange point and orbiting there, the entire spacecraft cools down to its working temperature of 40 K. This temperature is required to be able to perform Infra-Red observations between the wavelength of 0.6 μm up to 28.6 μm .

Near Infra-Red Camera (NIRC*am*) is the primary imager of JWST, working in the wavelength range of 0.6 to 5 μm . It is also a spectrometer. It is equipped with coronagraphs, to mask a centered bright object enabling to take pictures and measurements of faint sources nearby. The instrument is operating at 37 K (Burriesci 2005) and aims to detect light of the earliest stars and galaxies during their formation, to study the population of stars of nearby galaxies and in the Milky Way and also objects of the Kuiper Belt. The instrument, also used for metrology to align the elements of the segmented mirror, is provided by Arizona State University and Lockheed Martin's Advance Technology Center.

Near Infra-Red Spectrograph (NIRSpec) operates between 0.6 and 5.3 μm (Birkmann et al. 2016) and can perform analysis of a single object but is able also to observe simultaneously 100 sources using the microshutter array capabilities. The instrument is working around 42.8 K. It will study thousands of galaxies during the 5-year nominal mission. The instrument is a contribution

of ESA, built by Airbus Defence and Space while the microshutter arrays are provided by the Goddard Spaceflight Center.

Near Infra-Red Slitless Spectrograph/Fine Guidance Sensor (NIRISS/FGS) is both a camera and a spectrograph designed to capture images of bright objects. It is operating at around 40 K and between 0.6 μm and 5 μm but some observations for the observation of exoplanets is optimized between 0.6–2.5 μm (Maszkiewicz 2012). NIRISS will contribute to various science objectives like the detection of the first light and to the science of the exoplanets. The FGS is a camera system used to determine the right pointing direction by identifying selected stars and ensuring the exact and stable pointing of the entire telescope. The instrument is a contribution of the Canadian Space Agency.

Mid Infra-Red Instrument (MIRI) is equipped with cameras, spectrographs, coronagraphs, and an integral field unit allowing to work as a kind of Spectro-imager (giving an image of a field of view for each single wavelength) (Wright et al. 2008). It is working over a range of 4.6 to 28.6 μm . It operates at a lower temperature than the other instruments. The detector stage is precooled at 18 K and the nominal working temperature is 7 K. MIRI is fulfilling several objectives of JWST, observing the redshifted light of ancient and distant galaxies, and also young stars while forming. It will detect faint light of comets and study Kuiper Belt bodies. The instrument is a

wide international cooperation between the USA and European countries coordinated by ESA.

These instruments and the overall spacecraft are designed to fulfil the four large science objectives enlightened in the decadal survey 2001 (National Research Council 2001): “NGST is the top priority for this decade because it will reveal the first epoch of star formation and trace the evolution of galaxies from their birth to the present. It will also provide a unique window onto the birth of stars and planets in our own galaxy. Having NGST’s sensitivity extend to 27 μm would substantially improve its ability to study Kuiper Belt objects (KBOs) in our solar system, the formation of stars and planets in our galaxy, and the dust emission from galaxies out to redshifts of 3.” Note that NGST was named, in 2002, after James Webb, former administrator of NASA during the Apollo Era. The design of the instruments and the global shaping of the current program lead also to major contribution to the study and characterization of some of the closest exoplanets.

Kaapvaal Craton, South Africa

Nicholas Arndt
Maison des Géosciences, LGCA, Université
J. Fourier, St-Martin d'Hères, France

Definition

The Kaapvaal ► [craton](#) in South Africa is, along with the ► [Pilbara craton](#) of Western Australia, the only areas where mid-Archean (3.6–2.5 Ga) volcanic and sedimentary rocks are relatively well preserved. The craton covers an area of about $1.2 \times 10^6 \text{ km}^2$ and is made up of several strongly deformed early Archean (3.0–3.5 Ga) greenstone belts intrusive into tonalitic gneisses (ca. 3.6–3.7 Ga) and cut by a variety of granitic plutons (3.3–3.0 Ga). The craton formed and

stabilized between about 3.7 and 2.6 Ga when major granitoid batholiths intruded, and deformation thickened the crust. At the same time, a thick, stable harzburgitic (► [olivine](#)-orthopyroxene peridotite) keel formed the lower part of the lithosphere. Subsequent evolution from 3.0 to 2.7 Ga involved collision with surrounding cratons and the development of basins filled with thick sequences of both volcanic and sedimentary rocks. Similarities of rock records of the Kaapvaal and Pilbara cratons suggest that they were once part of a single continent called Valbara. Barberton, the largest greenstone belt in the craton, is well known for its ► [komatiites](#) (ultramafic volcanic rocks) and traces of early life preserved in ► [cherts](#) and other sedimentary rocks. Also present in the Kaapvaal craton is the Bushveld complex, an enormous mafic-ultramafic layered intrusion, and the 2.0 Ga Vredefort meteorite impact crater, the largest on Earth (300 km in diameter).

Kant-Laplace Nebular Hypothesis

Solar system

History

In 1755, the philosopher Immanuel Kant (1724–1804) brought out a work of his early youth, *Allgemeine Naturgeschichte und Theorie des Himmels* (Universal natural history and theory of the heavens) in which he expressed his ideas concerning the solar system's origin (Kant 1755). His cosmogony was entirely guided by Newton's mechanics: Kant assumed that the origin matter was diffused all over space, where it formed a kind of chaos. The constituent particles of this chaos, initially at rest, came to attract each other under the effect of gravitation and developed rotational motion. This motion, accelerating, created a circular ring in which breaking up produced in its turn planets and their satellites. Kant, in his cosmogonic hypothesis, was prompted by an analogical principle and the search of a systematic organization. He proposed that every system has a center and is reproduced in a hierarchical way, passing analogically from the Earth-Moon system, to the solar system, then to the distribution of stars in the Milky Way, and lastly from the galaxies (still called at that time nebulae) around the center of the universe: Kant's cosmogony aimed at stating a cosmic order.

If Kant said his hypothesis was scientific, in reality it was impossible to be confirmed by

observations at that time: it was only speculative. Moreover, it did not abide by certain laws of mechanics, such as the angular momentum conservation: How could particles shielded from all external effects begin a rotational motion? The French mathematician Pierre Simon Laplace (1749–1827) proposed in 1796 a cosmogonic hypothesis close to Kant's, without knowing the latter's work (Laplace 1824). His cosmogony appeared immediately more scientific, especially because Laplace limited himself to consider the solar system's structure, but not the universe's organization. Furthermore, he avoided the problem of setting the primitive nebula in motion, considering it already in a uniform rotation. His approach was different from Kant's because it was based more on a reasoning of probability (planets and satellite's revolution and rotation direction, known at that time) than on an evolutionary viewpoint. Aspects of the cosmogonic hypothesis quickly called the “Kant-Laplace's hypothesis” and discussed throughout the nineteenth century are still globally accepted today (Merleau-Ponty 1983; Michel 1975; Poincaré 1911; Wolf 1886).

[Kaolin](#)

Definition

Kaolinite is an extremely common layered silicate clay mineral with the chemical composition $\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4$. It consists of one tetrahedral sheet linked through oxygen atoms to one octahedral sheet of alumina octahedra. The name is derived from Chinese *Gaoling* meaning “high hill,” a mountain located in Jingdezhen, Jiangxi province, China. Kaolinite has a low cation exchange capacity. It is a soft, usually white mineral produced by the chemical weathering of aluminum silicate minerals such as feldspar. It is often colored reddish-orange by the presence of traces of iron oxides but may range from white, yellow, or light orange when lesser amounts of iron are present. Kaolinite occurs abundantly in soils formed from chemical weathering of rocks in hot, humid climates.

Kelvin-Helmholtz Timescale

Daniele Galli
INAF Osservatorio Astrofisico di Arcetri, Largo
E. Fermi 5, Italy

Definition

The Kelvin-Helmholtz timescale is the time required for a star to radiate its own gravitational energy. It is defined as the ratio of the star's gravitational energy GM^2/R (where M and R are the stellar mass and radius, respectively, and G is the gravitational constant), and the star's luminosity L (energy radiated per unit time):

$$t_{\text{KH}} = GM^2/RL$$

For the present-day Sun, $t_{\text{KH}} = 30$ Myr. A star with no internal energy sources (e.g., a pre-Main Sequence star before turning on nuclear reactions) slowly contracts on a Kelvin-Helmholtz timescale, radiating away all its gravitational energy. Suggested reading: Stahler and Palla (2004).

History

This concept was elaborated by the physicists William Thomson, Lord Kelvin (1824–1907) and Hermann von Helmholtz (1821–1894) from their investigations on the age of the Sun and the Earth and definitely formulated by the pioneer astrophysicist August Ritter (1826–1908). See Shaviv (2008).

Asteroseismology · Exoplanets · Photometry ·
Spectroscopy · Transiting planets

Definition

Kepler was a NASA mission to discover and characterize transiting planets around other stars (exoplanets), with a special emphasis on rocky planets where water could be liquid on the surface and life as we know it might be comfortable. Kepler also supported programs for asteroseismology and general astrophysics. It discovered more than 2000 planets making it the most prolific exoplanet discovery instrument so far.

History

Serious thinking about the feasibility of using very precise photometry to detect small changes in brightness when planets transit in front of their stars dates back more than 35 years (e.g., Borucki and Summers 1984). Subsequent proposals for space missions to search for small transiting planets, such as FRESIP (Borucki et al. 1996) in the 1990s, were viewed as technologically premature. However, this objection was answered by careful experiments with ► [CCDs](#), which demonstrated that the photometric precision required to detect a planet like the ► [Earth](#) passing in front of a star like the Sun could be achieved in a laboratory simulation of the mission. Scientific interest in the mission was piqued by the discovery of the first transiting planet, HD 209458 (e.g., Charbonneau et al. 2000), and *Kepler* was selected as NASA's tenth *Discovery* class mission. *Kepler* was launched successfully on a Delta II from Cape Canaveral in March 2009 and had

sufficient consumables to operate for a decade. It ended its operations in October 2018.

Overview

Kepler is a NASA satellite which discovered more than 2000 exoplanets over the span of 4 years. In 2012, a problem with reactions wheels prevented *Kepler* from continuing its nominal mission. However, an extended mission was approved in 2014, named K2, and it discovered a few hundred more planets until its end in 2018. *Kepler* has revolutionized our understanding of planetary systems, offering exquisite statistics. In particular, it showed that one of the most common observed exoplanet populations are the super-Earths and mini-Neptune populations.

Basic Methodology

The design of *Kepler* was driven by the goal of discovering an Earth-like planet transiting a Sun-like star in an orbit that would allow water to be liquid on the surface of the planet. The goal of detecting planets with orbital periods as long as a year set the requirement that the mission duration should be at least 4 years, so that at least three transits could be detected. The probability that the inclination of a 1-year orbit is properly aligned for transits to occur is less than 1%, and this set the requirement that at least 100,000 solar-type stars should be monitored continuously in order to yield enough planet detections to provide a statistically meaningful result for the case where Earth analogs are rare. This led to the requirement for a telescope with a wide field of view, on the order of 100 square degrees. To achieve the photometric precision needed to detect reliably a dimming as small as an Earth transit, 84 parts per million, a meter-class telescope was required. The *Kepler* photometer uses a Schmidt telescope with an array of 42 CCDs in a curved focal plane. The spacecraft is in an Earth-trailing orbit, which provides a much more stable environment than a low Earth orbit. The spacecraft is rotated to a new orientation four times a year in order to maintain

Kepler, Fig. 1 The *Kepler* flight unit (<https://science.nasa.gov/get-involved/toolkits/spacecraft-icons>)

illumination of the solar panels. The target area is more than 55° north of the ecliptic, and the focal plane is well protected from solar illumination by a sun shield. Figure 1 shows an illustration of the *Kepler* flight unit.

To aid selection of an optimized list of targets similar to the Sun, the Kepler Input Catalog (KIC) was prepared before launch. The KIC contains all the known stellar objects in the *Kepler* field of view, based on existing catalogs. This information was supplemented by stellar classifications of more than two million stars bright enough to be good targets, based on more than 50 million measurements of accurate positions and magnitudes in a set of filter-defined wavelength bands in the Sloan Digital Sky Survey plus a custom gravity-sensitive filter (e.g., Athay and Canfield 1969). These observations were obtained with KeplerCam on the 1.2-m telescope at the F. L. Whipple Observatory on Mount Hopkins in Arizona.

Because of telemetry limitations, full images were transmitted to the ground only after spacecraft maneuvers, nominally once per month, in order to confirm proper reacquisition of the target field. In normal operation, a limited number of pixels are saved around each target for later

transmission to the ground for processing. This allowed the development of the data reduction pipeline to continue during the mission, thus resulting in improved photometric performance as various subtle instrumental effects were understood and modeled. For most targets, the images were accumulated and stored on the spacecraft for an integration time of 30 min, but a limited number of targets could be sampled with a cadence of 1 min, thus providing better time resolution for the light curves of transient events, such as the ingress and egress of transits. After the first year of operation on orbit, the photometric performance of all the data obtained by *Kepler* was close to the specification of 20 parts per million for a $V = 12$ magnitude solar-type star over an integration time of 6.5 h.

Key Research Findings

In the first year of operation, *Kepler* already had identified several hundred candidate-transiting planets. Many of the transit light curves implied planets smaller than Neptune. A key part of the *Kepler* mission is still an ongoing effort to confirm and characterize the candidates as true transiting planets, using a variety of ground-based and space-based observations. This includes reconnaissance spectroscopy aimed at the elimination of systems involving eclipsing binaries that masquerade as transiting planets, and to provide more precise classification of the stellar characteristics. The second aspect is quite important, because the accuracy with which planetary parameters such as radius and mass can be determined is often set by uncertainties in those parameters for the host star. Another important step in the follow-up of *Kepler* candidates is deep imaging with very high spatial resolution, with techniques such as adaptive optics, speckle imaging, and even HST (Hubble Space Telescope) imaging. This can reveal nearby companions that are hidden in the blur of the *Kepler* images, due to the large pixels, which are 4 arcsec^2 on the sky. The *Kepler* data also allows very precise astrometry, despite the large pixels, because of the extraordinarily large number of collected photons and continuous duty cycle.

Motion of the image centroids during transit events can often be measured to better than 0.0001 pixels. When combined with the high-resolution images, this is a powerful tool for detecting background eclipsing binaries, on the one hand, or for confirming that the target star is the source of the transits, on the other hand. In some cases, observations in the infrared with the now retired Warm Spitzer Space Telescope could be used to test whether the depth of the dimmings were achromatic, as expected for transits. The gold standard for confirming and characterizing a transiting planet is a spectroscopic orbit for the host star that yields a mass for the unseen companion that is consistent with a planetary interpretation. This final step usually requires substantial time on precious resources such as the HIRES spectrometer on the Keck I telescope, the HARPS spectrometer on the ESO La Silla 3.6 m telescope, or now ESPRESSO at the VLT. Limited access to such facilities dictates that not every candidate can be fully confirmed. Besides, the orbital amplitude of less than 10 cm^{-1} that the Earth induces in the Sun is just starting to be in reach of a few existing radial-velocity instruments (e.g., ESPRESSO), and it is clear that it will be challenging to disentangle planetary signals from the activity of the stars themselves (see ► [Activity, Magnetic](#), Cretignier et al. 2020) to allow velocity measurements at this level. For the smallest planets, the strategy is to eliminate as many as possible of the astrophysical false positives that might mimic Earth-like transits.

As of November 2021, *Kepler* and follow-up observations such as radial velocity measurements had confirmed about 2400 exoplanets in more than 1700 systems. An additional more than 2300 candidate exoplanets still await confirmation (see https://exoplanetarchive.ipac.caltech.edu/docs/counts_detail.html). Orbiting stars which were in the Kepler field of view, 361 candidates, and planets were found in the ► [habitable zone](#), for instance, Kepler-62 e and f (Borucki et al. 2013) or Kepler-186 f (Quintana et al. 2014). Amusingly, a habitable zone planet was recently rescued from its false positive status

(i.e., this planet was initially classified as a false positive by the Kepler pipeline). Its name is Kepler-1649 c and as most of its fellow Kepler habitable zone planets, it orbits a star significantly less massive than the Sun (Vanderburg et al. 2020).

Several dramatic breakthroughs in asteroseismology using *Kepler* data were reported in the same time frame (Gilliland et al. 2010; Davies et al. 2016; Yu et al. 2018).

A first problem with a reaction wheel which stabilizes the spacecraft was discovered on July 16, 2012. After several tests, the science data collection resumed. A second reaction wheel failed on May 11, 2013. The spacecraft was no longer fully operational.

However, on May 16, 2014, NASA announced the approval of extending the *Kepler* mission to the so-called K2 mission, which lasted until 2018. Although the photometric precision of the K2 mission was an order of magnitude poorer than that of the original mission, a much larger area of the sky has been observed. The K2 missions confirmed 476 planets, and 850 candidates remain to be confirmed.

Future Directions

The main legacy of *Kepler* is the frequency and characteristics of the population of extrasolar planets, from those with periods shorter than a few months to planets belonging to the family of Super-Earths and Mini-Neptunes. This information is critical for the design of future, much more expensive missions for astrometric and direct detection of exoplanets, such as the European PLATO mission.

Kepler 11: Multiple Transiting Planet System

Nader Haghighipour

Institute for Astronomy, University of Hawaii-Manoa, Honolulu, HI, USA

Definition

Kepler 11 system is the 11th planetary system detected by the *Kepler* space telescope (Lissauer et al. 2011). The central star of this system is Sun-like and hosts six planets, five with orbital periods between 10 and 47 days and one with a longer period. The Kepler 11 planetary system is the first discovered case of a star system with six transiting planets. Figure 1 shows an artist's rendering of this system. All discovered planets are larger than Earth. Their masses were estimated thanks to the observed transit timing variations, which were large enough due to the compactness of the system. These radii and masses measurements show that the six planets have low densities (Lissauer et al. 2013). The orbits of planets b–f would easily

Kepler 11: Multiple Transiting Planet System, Fig. 1 Artist's rendering of the Kepler 11 planetary system

Kepler 11: Multiple Transiting Planet System, Fig. 2 Schematic presentation of the orbits of Kepler 11 planets

fit inside the orbit of Mercury, with planet g only slightly outside of it (Fig. 2). Despite this close packing of the orbits, dynamical integrations indicate the system has the potential to be stable on a time scale of billions of years.

Kepler 16b: First Circumbinary Planet

Nader Haghighipour

Institute for Astronomy, University of Hawaii-Manoa, Honolulu, HI, USA

Definition

Kepler-16b is the first circumbinary planet discovered around a pair of low-mass and main-sequence stars using the Kepler space telescope (Doyle et al. 2011). Data from the Kepler spacecraft revealed transits of the planet across both stars, in addition to the mutual eclipses of the binary (Fig. 1). The planet has a mass of 0.33 Jupiter masses, comparable to Saturn in mass and size, and is in a nearly circular orbit with a period of ~229 days. The host binary consists of two eclipsing stars, 0.69 and 0.20 times as massive as the Sun, and has an eccentric (0.16) orbit with a period of 41 days. The motions of all three bodies are confined to within 0.5° of a single plane, suggesting

K

Kepler 16b: First Circumbinary Planet, Fig. 1 The light curve of Kepler 16. As shown here, the light curve, in addition to the eclipses of the two stars, shows the eclipse of each star by the planet as well (Doyle et al. 2011)

that the planet formed within a circumbinary disk. Kepler-16b is also the first circumbinary planet to have been detected in the habitable zone of its host binary (Haghighipour and Kaltenegger 2013). Although this planet is too large to be habitable, at least by terrestrial life forms, it may have natural

satellites that might be habitable. Figure 2 shows an artist’s rendering of the Kepler-16 circumbinary system. Figure 3 shows the size of this system compared with the solar system. A movie of the habitable zone of Kepler-16 can be found at <http://astro.twam.info/hz-ptype/>.

Kepler 186f: First Earth-Sized Planet in Habitable Zone

Nader Haghighipour

Institute for Astronomy, University of Hawaii-Manoa, Honolulu, Hawaii, HI, USA

Definition

Kepler-186f is the first Earth-sized planet in the ► [habitable zone](#) detected by the Kepler space telescope. This planet is the outermost of the five

planets transiting Kepler 186, a 0.47 solar radius, main sequence M1 star with a surface temperature of 3788 K. The inner four planets of this system were detected using the *Kepler* data from the first 2 years (Rowe et al. 2014; Lissauer et al. 2014). These planets are all smaller than 1.5 Earth radii and have orbital periods between 3.9 and 22.4 days. Kepler-186f was detected with an additional year of data (Quintana et al. 2014). Figure 1 shows an artist's rendering of this planetary system.

Conservative estimates suggest that the habitable zone of Kepler186 extends from 0.22 to 0.40 AU around this star (Kopparapu et al. 2013a, b). With an orbital period of ~130 days and a semimajor axis of ~0.35 AU, Kepler-186f is right in the star's habitable zone. Figure 2 shows a comparison between the flux received by this planet and those of other known potentially habitable exoplanetary systems. Bolmont et al. (2014) discuss the planetary system evolution and habitability in more detail than in Quintana et al. (2014). They found that the planet can sustain surface temperatures above the freezing point of water with 0.5–5 bars of carbon dioxide, depending on its nitrogen content.

Kepler 47: First Multi-circumbinary Planet System

Nader Haghighipour

Institute for Astronomy, University of Hawaii-Manoa, Honolulu, HI, USA

Definition

The eclipsing binary Kepler-47 is the first system detected to have multiple ► [circumbinary planets](#) (Orosz et al. 2012). The binary consists of a Sun-like star and a companion roughly one-third its size, orbiting each other every 7.45 days. The planets were detected using transit photometry when each planet transits the stars of the binary. Figure 1 shows some of the planetary transits of this system. The inner and outer planets of Kepler-47 system have radii 3.0 and 4.6 times that of Earth, respectively. The inner planet, Kepler-47b,

Kepler 47: First Multi-circumbinary Planet System, Fig. 1 The normalized flux near five representative transits of the inner planet (*upper*) and all three transits of the

outer planet (*lower*) are shown (Orosz et al. 2012). The deepest minima correspond to the eclipse of the planet-hosting star by the other star of the binary system

K

Kepler 47: First Multi-circumbinary Planet System, Fig. 2 Graph of the narrow (*dark green*) and empirical (*light green*) HZs of Kepler 47 binary system. Calculations show that the effect of the secondary star is minute indicating that the HZ of the system is in most part determined by the primary star. The figure also shows the orbits of the three planets of this system in *blue*, with the two stars indicated by *dots* (Orosz et al. 2019)

has an orbital period of 49.5 days. The outer planet’s orbital period is 303.2 days.
Calculation of the ► [habitable zone](#) (HZ) of the Kepler-47 binary by Haghighipour and

Kaltenegger (2013) has shown that the outer planet, Kepler-47c has been found to spend some time in the binary habitable zone (Fig. 2). Since this planet is larger than Earth, it cannot be

Kepler 47: First Multi-circumbinary Planet System, Fig. 3 Artist's rendering of the Kepler 47 circumbinary planetary system. (Figure courtesy of NASA)

habitable. However, it can have natural moons that could be habitable. A movie of the evolution of *the* habitable zone of this system can be found at <http://astro.twam.info/hz-ptype/>. Recently, a third planet was detected in the system between planet b and c (Orosz et al. 2019).

The detection of the Kepler-47 planetary system as the first with multiple planets in circumbinary orbits establishes that close binary stars can host complete (and even habitable) planetary systems. Figure 3 shows an artist's rendering of this system.

Kepler 9: First Transiting System Confirmed by TTV

Nader Haghighipour

Institute for Astronomy, University of Hawaii-Manoa, Honolulu, Hawaii, HI, USA

Definition

The planetary system of the star Kepler 9 is the first system confirmed by the Transit Timing Variation Method (TTV). The central star of this system, a solar-like star, hosts two Saturn-sized planets in 19.2- and 38.9-day periods, in a near 2:1 [mean motion resonance](#) (Holman et al. 2010). The analysis of the observational data indicated that the periods of these two planets are increasing and decreasing at average rates of 4 and 39 min per orbit, respectively. It was also shown that the transit times of the inner body display an alternating variation of smaller amplitude. Figure 1 shows these variations for both planets. The observed TTVs are characteristic of gravitational interaction of two planets near a 2:1 orbital resonance.

Further analysis of the Kepler 9 data pointed to the existence of a third planet, Kepler 9d, in a 1.59-day orbit. Kepler 9d is a [Super-Earth](#) with a radius 1.64 times that of Earth's (Torres et al. 2011).

Kepler 9: First Transiting System Confirmed

by TTV, Fig. 1 Variations in observed transit times “O” of planets Kepler 9b (blue crosses) and Kepler 9c (red dots) (Holman et al. 2010) compared to calculated transit times “C.” The three panels show three different ways of estimating the calculated transit times “C.” Top panel: The calculated transit times “C” were estimated with linear ephemerides (where $C = A + P \cdot t$, where A and P are constants, and t is the epoch of transit). Middle panel: The calculated transit times “C” were estimated using quadratic ephemerides. Bottom panel: The calculated transit times “C” were estimated using the outcome of a numerical simulation of the orbital evolution of the two planets with fitted planetary masses and orbits

Kepler, Johannes

Fernando B. Figueiredo
CITEUC, University of Coimbra, Coimbra,
Portugal

History

Johannes Kepler (1571–1630), born in December 27, 1571 in Weil der Stadt (Germany), is one of the fathers of the modern physical astronomy. He revolutionized astronomy, by breaking with the dominant notion of circular motion of the planets, discovering the three laws of planetary motion that bear his name (published in 1609 and 1619): (1) planets move in elliptical orbits with the Sun at

a focus; (2) the line connecting a planet with the Sun will sweep over equal areas in equal periods of time; (3) the square of a planet's period is proportional to the cube of its mean distance from the Sun.

In March 7, 2009 NASA launched the Kepler Mission specifically designed to survey the region of our Milky Way galaxy in order to discover Earth-size planets in or near the habitable zone of other stars.

Kepler-10

Nader Haghighipour

Institute for Astronomy, University of Hawaii-
Manoa, Honolulu, HI, USA

Definition

Kepler-10, an old (11.9 ± 4.5 Gyr) sunlike main-sequence star, is the central star of the

tenth planetary system discovered by the *Kepler* space telescope (Batalha et al. 2011). This star has a temperature of 5627 ± 44 K, mass of 0.895 ± 0.060 solar masses, and radius of 1.056 ± 0.021 solar radii. Kepler-10 is host to two planets, Kepler-10b (Batalha et al. 2011) and Kepler-10c (Fressin et al. 2011). The latter planet has a period of 45 days. ► [Radial velocity](#) measurements from HARPS-North and Keck-HIRES do not seem to agree on its mass, only that it should be below 20 Earth masses.

Overview

Kepler-10b was the first rocky planet detected by the Kepler telescope and was confirmed with radial velocity follow-up observations from Keck-► [HIRES](#). The mass of the planet was measured with a precision of around 30%, which was insufficient to constrain models of its internal structure and composition in detail.

Kepler-10, Fig. 1 Artist's rendering of the surface of Kepler-10b

In 2014, Dumusque et al. used the data from ► [HARPS](#) and obtained the mass and radius of planet *b* to be 3.33 ± 0.49 Earth masses and 1.47 ± 0.03 Earth radii, respectively. With these values, the density of the planet is $5.8 \pm 0.8 \text{ g cm}^{-3}$, which is very close to the value predicted by models with the same internal structure and composition as the Earth. More recently, Weiss et al. (2016) used additional precise radial velocity measurements from Keck-HIRES to revisit the properties of the planets. In particular, they found a higher mass for Kepler-10c than in Dumusque et al.; however, the data from HARPS and Keck-HIRES do not agree which could be due to a source of noise not well accounted for. They also hypothesize the presence of an additional third planet due to the presence of transit timing variations on Kepler-10c.

The orbital period of planet Kepler-10b is slightly larger than 20 h making this planet one of the closest planets to their host stars. The close proximity of this planet to star Kepler-10 causes the surface of the planet to have a very high temperature. Figure 1 shows an artist's rendering of the surface of Kepler-10b.

Kepler-37b: A Moon-Sized Planet

Nader Haghighipour

Institute for Astronomy, University of Hawaii-Manoa, Honolulu, Hawaii, HI, USA

Definition

Kepler-37b, with a radius of ~ 0.296 Earth radii (Stassun et al. 2017), slightly larger than the radius of the Moon, is the smallest extrasolar planet discovered as of February 28, 2013 (Barclay et al. 2013). Figure 1 shows the sizes of three planets of the system. Kepler-37 is a main-sequence star, slightly cooler and smaller than the Sun. It has an effective temperature of $\sim 5417 \text{ K}$, and its mass and radius are 0.87 and 0.79 times the mass and radius of the Sun, respectively. This star is host to four planets, Kepler-37b, c, d, and e. Kepler-37e was discovered using transit timing variations by Hadden and Lithwick (2014). The radii (in Earth radius) and orbital periods (in days) of planets b, c, and d are (0.296, 0.75, and 1.94) and (13.37, 21.30, and 39.79), respectively. Observational data cannot be used to constrain the mass of Kepler-37b. However, models of the interior of planetary systems suggest that a mass a few times larger than that of the Moon would result in an unreasonably high bulk density for the planet.

Definition

The Kepler-444 planetary system is the oldest known system of terrestrial-size planets. The host star, Kepler-444, is an ancient (11.2 ± 1.0 Gyr) Sun-like star from the stellar population of the Milky Way's thick disk. Based on photometry from the *Kepler* spacecraft, a system of five transiting planets was discovered orbiting Kepler-444, their sizes ranging between those of Mercury and Venus. The system is highly compact, with all planets orbiting the parent star in less than 10 days.

History

Transit-like signals, indicative of five planets orbiting *Kepler* Object of Interest 3158 (KOI-3158; named Kepler-444 after it had been confirmed), were detected in nearly continuous, 4-year-long *Kepler* photometry (Tenenbaum et al. 2013). The five planets were subsequently identified as planet candidates based on the examination of *Kepler* pixel-level and light curve data.

Kepler-444, Fig. 1 Phase-folded transit light curves of the five planets orbiting Kepler-444 (Campante et al. 2015). From panels (a) to (e): transits of planets Kepler-444b, Kepler-444c, Kepler-444d, Kepler-444e, and Kepler-444f, respectively. Observed data are shown as gray dots. Blue dots correspond to a binning of the observed data. The best-fitting transit model is shown as a red line. (© AAS. Reproduced with permission)

K

Campante et al. (2015) validated the system as a true five-planet system orbiting the target star and provided a detailed characterization of its planetary and orbital parameters based on an analysis of the transit photometry (see Fig. 1).

Overview

Kepler-444 (also known as HIP 94931, KIC 6278762, KOI-3158, and LHS 3450) is a cool main-sequence star of spectral type K. With an apparent magnitude $V = 8.86$ and lying at a distance of 35.7 ± 1.1 pc in the constellation Lyra, it is both

among the brightest and nearest *Kepler* planetary hosts. Kepler-444 is iron-poor ($[\text{Fe}/\text{H}] = -0.55 \pm 0.07$ dex) and moderately enhanced in terms of α -process elements ($[\alpha/\text{Fe}] = 0.26 \pm 0.07$ dex), indicating membership of the old stellar population of the Galactic thick disk (the star's kinematics corroborate this; Campante et al. 2015).

A precise ($\sim 9\%$) age of 11.2 ± 1.0 Gyr has been measured for Kepler-444 from detailed asteroseismology based on *Kepler* photometry (Campante et al. 2015). The old age of Kepler-444 suggests that thick-disk stars were among the hosts to the first planets in the Galaxy. The same

Kepler-444, Fig. 2 Semi-major axes of planets in the highly compact multiple-planet systems Kepler-444, Kepler-11, Kepler-32, Kepler-33, and Kepler-80 (Campante et al. 2015). Semi-major axes of Solar System

planets are shown as reference. The vertical dotted line marks the semi-major axis of Mercury. Symbol size is proportional to planetary radius. (©AAS. Reproduced with permission)

study quotes values for the stellar mass and radius of 0.758 ± 0.043 solar masses and 0.752 ± 0.014 solar radii, respectively. A thorough reappraisal of the fundamental stellar properties of Kepler-444 (Buldrin et al. 2019), based on revised spectroscopic parameters and the added constraint from its *Gaia* parallax, led to fully consistent values. The latter study further suggests that Kepler-444 bore a convective core during a significant fraction of its life on the main sequence, which could potentially affect the internal transport of angular momentum in later stages of stellar evolution.

Kepler-444b, the innermost and smallest planet (within 2σ of the size of Mercury), had its radius measured with a precision of ~ 100 km (Campante et al. 2015). All five planets are sub-Earth-sized with monotonically increasing radii as a function of orbital distance: 0.403 (Kepler-

444b), 0.497 (Kepler-444c), 0.530 (Kepler-444d), 0.546 (Kepler-444e), and 0.741 (Kepler-444f) Earth radii. Kepler-444c, d, and e are similar in size to Mars. Kepler-444f has a size intermediate to Mars and Venus. The system is highly compact, both in terms of its architecture and dynamically (see Fig. 2). All planets orbit the parent star in less than 10 days, or within 0.08 au. Moreover, adjacent planet pairs are close to being in strong 5:4, 4:3, 5:4, and 5:4 first-order, mean-motion resonances (as one moves away from the star).

Kepler-444 is in fact the primary (Kepler-444A) in a triple system (Campante et al. 2015; Dupuy et al. 2016), which also harbors a spatially unresolved pair of M dwarfs (Kepler-444B and C) at a projected distance of 1.8 arcsec (~ 66 au). Such configuration poses a challenge regarding the early evolution of the system (Dupuy et al. 2016; Papaloizou 2016), as planetary formation and

migration in a (likely) truncated protoplanetary disk are not yet fully understood.

Based on a transit-timing analysis, Mills and Fabrycky (2017) were able to determine the masses and densities of planets d and e (both with a composition consistent with that of the Solar System terrestrial planets or even of a pure water planet), placing upper limits on the properties of the remaining planets. Determining the planetary masses from radial velocities would be extremely challenging, the predicted semi-amplitude being ~ 0.3 m/s even with all five planets contributing. They infer from the mass ratio of planets d and e that the system experienced significant orbital period changes after a formation scenario involving migration, or else formed in situ.

Finally, observations in H γ Lyman- α made with the *Hubble* Space Telescope led to the detection of significant flux variations during the transits of Kepler-444e and f, as well as at times when no planets were transiting (Bourrier et al. 2017). If planetary in origin, this signal could be due to absorption by hydrogen exospheres trailing the two outermost planets. Both planets would then have to contain substantial amounts of water to replenish their atmospheres, making them bona fide waterworlds.

Keplerian Orbits

David W. Latham
Harvard-Smithsonian Center for Astrophysics,
Cambridge, MA, USA

Definition

Johannes Kepler is famous for his three laws of orbital motion for the planets in the solar system. The first two were presented in his *Astronomia nova*. In essence, they state that planets move in elliptical orbits, sweeping out equal areas in equal times. The powerful third law surfaces in his *Harmonice Mundi*, where Kepler shows that the square of the planet's orbital period is proportional to the cube of the orbit's semimajor axis. Newton reformulated the problem in terms of masses and showed how the masses of the orbiting bodies enter into the third law. When objects follow Newton's formulation and move

in orbits that follow Kepler's laws, they are said to have Keplerian orbits.

Kerogen

Emmanuelle J. Javaux
Palaeobiogeology-Palaeobotany-
Palaeopalynology, Geology Department,
Université de Liège, Liège, Belgium

Definition

The kerogen is the macromolecular organic matter that is insoluble in organic solvents (soluble portion is known as ► [bitumen](#)). Kerogen is present in ancient sedimentary rocks and meteorites. It is composed of smaller molecules that have covalently bound together during synthesis (including biosynthesis), diagenesis, and thermal alteration processes. In sediments, kerogen is the fossil organic matter source of oil and natural gas. The degree of hydrogen loss and aromatization is often used as an indicator of thermal maturity. The degree of structural order versus disorder for aromatic sheets is a defining characteristic of different kerogens identifiable by Raman spectroscopy. Organic-walled fossils resistant to acid maceration (such as acritarchs, spores) are observed in some kerogens.

Chemical Formula

HCCO

Definition

The ketenyl radical is a short-lived chemical species on Earth and an important intermediate in combustion chemistry and astrochemistry. Its rotational spectrum has been characterized in the laboratory, showing that it closely approximates a prolate symmetric top (Endo and Hirota [1987](#)). On Earth, the HCCO radical is produced during the oxidation of acetylene by the reaction between C_2H_2 and O (Peeters et al. [1994](#)), while in the interstellar medium, where it has been recently detected (Agúndez et al. [2015](#)), it is thought to be formed in the gas phase through the reaction between OH and C_2H (Wakelam et al. [2015](#)).

Kinetic Isotope Effect

Kensei Kobayashi
Yokohama National University, Yokohama, Japan

Synonyms

[Isotope effect](#); [Isotopic effect](#)

Definition

A kinetic isotope effect (*KIE*) is an effect observed due to differences in the chemical reaction rates of a molecule with a heavier isotope (k_H) relative to one containing a lighter isotope (k_L):

$$KIE = k_L/k_H.$$

Molecules with different isotopic compositions generally react with other molecules in the same manner, but their reaction rates show differences due to their mass differences and sometimes also due to the lower natural abundance of certain isotopes. For example, $^{13}C^{16}O_2$ is heavier than $^{12}C^{16}O_2$ by about 2.3%, and the abundance ratio of $^{13}C^{16}O_2/^{12}C^{16}O_2$ is about 1.1%. In photosynthesis by plants, the fixation rate of $^{13}C^{16}O_2$ is slower than that of $^{12}C^{16}O_2$, which causes a decrease of the $^{13}C/^{12}C$ ratio in biosynthesized glucose. Thus, the isotopic composition of natural samples is an important parameter in studying their origins. For example, the isotopic composition of organic carbon can be used to distinguish whether it is of abiological or biological origin, and even by which carbon fixation pathway it is derived.

Komatiite

Nicholas Arndt
Maison des Géosciences, LGCA, Université
J. Fourier, St-Martin d'Hères, France

Keywords

Archean volcanic rock · Mantle temperature

Definition

Komatiite is a volcanic rock of ultramafic composition. It is distinguished from the more common basaltic magma by a higher content of MgO (>18%) and correlated low contents of most other elements.

Overview

Komatiite is relatively common in Archean greenstone belts, rare in Proterozoic belts, and virtually absent in younger regions. The type area is the 3.5-Ga Barberton greenstone belt of South Africa where the rock type was first discovered; their name comes from this type locality: the Komati River in Kaapvaal Craton. Examples are now

known in most Archean ► [greenstone belts](#), and komatiitic ► [basalt](#), the fractionation product of komatiite, occurs in Proterozoic belts of northern Canada. The komatiites of Gorgona Island off the coast of Colombia are the sole well-documented examples of Phanerozoic komatiite. So far, the older komatiitic magma would be the 3.8 Ga-old parental magma of the Nuvvuagittuq sills (O'Neil et al. 2011). The komatiites, older than 3.4 Ga, have different chemical compositions from younger komatiites, being characterized by high CaO/Al₂O₃ and low Al₂O₃/TiO₂ (Sossi et al. 2016). Important ore deposits of Ni-Cu sulfides are found in komatiites in Australia and Canada. Komatiite normally erupts in subaqueous lava flows, differentiating into an upper layer with spinifex texture and a lower ► [olivine](#) cumulate layer. Spinifex texture, emblematic of komatiite, consists of large and elongated, up to several centimeters long, bladed, skeletal olivine crystals in a matrix of fine clinopyroxene and glass (Fig. 1). The texture forms during crystallization of hot lava in the steep thermal gradient within the upper part of the flow. The eruption temperature of komatiite can be estimated from the MgO content of the parent liquid (Campbell and Griffiths 2014): The maximum MgO content, inferred from examples in South Africa and Australia, is greater than 30%, which corresponds to a temperature higher than 1,670 °C (Wilson 2019), some 400 °C hotter than that of typical basalt.

Komatiite results from partial melting in unusually hot parts of mantle, most probably in mantle plumes. The abundance of komatiite in the Archean is a manifestation of high temperatures in the mantle at that time. On the other hand, the presence of diamond in Archean komatiites indicates that they derived from a high-pressure source (Capdevila et al. 1999; Cartigny 2010). The release of Ni from hydrothermally altered komatiite in the oceanic crust may have been important during the early evolution of ► [life](#). The decrease in the abundance of komatiite may have provoked a decline in the activity of methanogenic Archaea, which was linked to the rise of oxygen in the early Proterozoic.

Korarchaeota

Ricardo Amils
Departamento de Biología Molecular,
Universidad Autónoma de Madrid,
Madrid, Spain

K

Definition

Korarchaeota has been incorporated into the TACK superphylum of Archaea. So far the members of this phylum have only been detected in hydrothermal environments. Korarchaeota were originally discovered by microbial community analysis of ribosomal RNA genes from environmental samples of a hot spring in Yellowstone, but recently they have been identified in other hydrothermal environments, like Kamchatka, Russia. No pure cultures from this phylum have been isolated yet. Methane metabolism genes have been identified in the genome of a stable enrichment mixed culture of Korarchaeota. The detection of methanogenesis in one of the most deeply rooted archaeal phyla supports the hypothesis that this metabolism was an early energy conservation system.

Kozai Mechanism

Rory Barnes
Astronomy Department, University of
Washington, Seattle, WA, USA

Definition

In planetary dynamics, the Kozai mechanism is a coupling between ► [orbital](#) inclination and eccentricity that can drive large oscillations in both quantities. For low eccentricity and inclination, motion in the plane and out of the plane are independent, but if either value is large (especially if both are), angular momentum can be readily exchanged, and the two parameters could change significantly more than expected in the decoupled case. For example, one mechanism for exciting the eccentricity of a planet orbiting a star is perturbations from a binary stellar companion whose orbit is highly inclined with respect to the planet's orbital plane.

[K, REE, and P-rich lunar material](#)

Definition

KREEP is a lunar rock having very high concentrations of incompatible elements. Its name is an acronym for the incompatible elements K (potassium), rare-earth elements (REE), and P (phosphorous).

Overview

Numerous samples of KREEP material were collected during Apollo 12, 14, 15, 16, and 17 missions, yet a few of them were pristine endogenous igneous rocks (the so-called KREEP basalts), the majority being polymictic breccia (Warren and Wasson 1979). Typical mineralogical modal composition of KREEP basalts is 86–98% of pyroxene and plagioclase, the remaining being often cristobalite (a high-temperature phase of quartz, SiO₂), ilmenite (FeTiO₃), minor phosphate, iron and sulfide, and groundmass (data from sample 14,276, Apollo 14; samples 15,382 and 153,866, Apollo 15). Typical concentrations of K₂O and

P_2O_5 are 0.5–1 wt%, while Rb has abundances of 12–25 ppm and Lanthanum up to 300 times the chondritic abundance, well above the abundances found in the anorthosites and gabbros of the lunar highlands and the mare basalts. Ages of the KREEP basalts are usually around 3.95 Ga, but Rb-Sr and Sm-Nd chronology of an Apollo 17 KREEP basalt gave even older 4.08–4.13 Ga ages (Shih et al. 1992) with model age for the source of the KREEP basalt at 4389 ± 45 Ma (Borg et al. 2015).

The origin of KREEP basalts is intrinsically related to the origin of the Moon itself. When the Mars-size protoplanet Theia hit the Earth and impact debris formed the Moon, the large amount of potential energy liberated was transformed into thermal energy which brought to the formation of a magma ocean (the Lunar Magma Ocean or LMO; e.g., Elkins-Tanton et al. 2011). As crystallization of the LMO proceeded, olivine and pyroxene precipitated and sank to form the lunar mantle. Less dense anorthositic plagioclase floated, forming an anorthositic crust. Residual melt was progressively enriched by incompatible elements (i.e., those that partition preferentially into the liquid phase) forming the “KREEP”-rich

layer ultimately trapped at the base of the anorthositic crust. Subsequent melting of this layer has produced KREEP-rich basalts.

The ubiquitous presence of KREEP samples in the diverse landing sites of the Apollo missions suggested that this KREEP material had been formed by melting of a widespread layer beneath the Moon’s crust. However, this assumption was denied by the results of the thorium mapping by the Lunar Prospector mission’s Gamma-Ray Spectrometer (GRS) (Fig. 1). Thorium is a high incompatible element and thus a good tracer of the incompatible element-rich material, such as KREEP. Results of the thorium distribution on the Moon showed that most of it is concentrated, for unknown reasons, underneath the *Oceanus Procellarum* and the *Mare Imbrium*. This is a unique lunar geological province that is now known as the *Procellarum KREEP Terrane* (Jolliff et al. 2000). These results casted doubts on the representativity of Moon petrology of the Apollo mission samples. To reconcile the ubiquitous presence of KREEP samples among the Apollo sites and the apparent localized magmatic source, it must be considered the fact that most of KREEP samples are polymictic breccia and thus

K

Kreep, Fig. 1 Thorium (Th) concentrations on the surface of the Moon as measured by the Gamma-Ray Spectrometer (GRS) embarked on the Lunar Prospector mission. Thorium correlates with the location of KREEP. (Credit NASA)

derived from large impacts that could have dispersed KREEP material very far, well beyond the original magmatic source region.

[Cretaceous/Paleogene \(KPg\)](#); [Cretaceous/Tertiary boundary \(KT\)](#); [K/T boundary](#)

Definition

The Cretaceous/Tertiary boundary (KT), also often called the Cretaceous/Paleogene (K/Pg) boundary, is a stratigraphic interval marking the

contact between the Mesozoic and Cenozoic eras, 66 Ma ago. The KT boundary is characterized by the last major mass extinction in the Earth history that saw the demise of the nonavian dinosaurs along with 50–60% of the Earth fauna and flora.

Overview

Over most of the Earth surface, this stratigraphic interval is composed of a mm- to cm-thick clay layer containing evidence of a large-scale asteroid or comet impact on Earth. The KT clays contain a significant enrichment in platinum group elements (Pt, Ir, Os, Rh, Ru, and Pd), better known as the KT iridium peak, amounting to several tens of ppb (parts per billion). This enrichment is clearly indicative of a meteoritic or extraterrestrial contribution to the sedimentation, being iridium rare on the Earth surface (about 1–2 ppb). Recently, the Ir positive anomaly was found also within the peak-ring sequence of the Chicxulub crater, drilled by IODP-ICDP in 2016 (Goderis et al. 2021). Other impact markers such as shocked quartz and zircon, indicative of the high pressures generated by the impact (> 5 GPa) as well as highly oxidized Ni-rich magnesioferrite spinels (often called cosmic spinels, which likely formed in the atmosphere, e.g., Toppani and Libourel 2003), also concentrate in the KT clay layer. This clay unit forms the distal ejecta material spread all over the Earth after the Chicxulub impact in the Yucatan Peninsula, Mexico. Closer to the impact site, around the Gulf of Mexico region, the KT boundary thickens to several meters of high-energy sediments. This proximal succession is composed at the base of glass spherules similar in composition to the Chicxulub impactites. This ejecta unit is followed by thick coarse sandstone units, most likely deposited by high-energy tsunami waves triggered by the cratering event. The Ir anomaly occurs just above the coarse sandstone, diluted by the high sediment input generated all over the Gulf region. In marine settings, the abruptness of the mass extinction is clearly visible in the microplankton that disappears precisely at the moment of deposition of the KT clay layer. The extinction of the

calcareous primary producers is widespread and affected the whole marine food chain. The decrease in microplankton was short lived and oceanic biologic productivity recovered after the KT boundary. The layer directly above the KT boundary is characterized by opportunistic organisms, before the recovery phase indicated by the appearance of new Paleogene species. On the continent, the extinction of diverse vegetation and the destruction of forest also coincide with the ejecta deposition. A fern-spore spike occurs at the boundary, illustrating the demise of the vegetation.

Definition

The Kuiper Belt is the region in the solar system beyond the orbit of Neptune that contains bodies rich in volatiles orbiting the Sun, also known as transneptunians.

Overview

In the last decades, the outer solar system has been found to be densely populated by a multitude of icy bodies called Kuiper Belt objects, Edgeworth-Kuiper objects, or transneptunian objects. The discovery of these bodies revolutionized our understanding of the solar system and most ideas relative to the evolution of the protoplanetary nebula. The general interest in the outer solar system grew rapidly in the scientific community. In fact, these bodies located so far from the Sun are considered as the fossils of the protoplanetary disk, which, consequently, can provide important information on the processes that dominated the evolution of the early solar nebula as well as of other planetary systems around young stars.

Transneptunian objects (TNOs) as well as asteroids and comets can be considered as the building blocks (planetesimals) of the solar system, offering clues to the composition of the matter from which planets formed some 4.6 billion years ago. The investigation of the physical properties of these icy bodies, as remnants of the outermost planetesimal swarms, is essential to understanding the formation and the evolution of the whole population of solar system bodies.

TNO science has rapidly evolved in recent years, linking together different research areas. The attempt to know this population's properties and history is one of the most active research fields in planetary science.

The first transneptunian object to be discovered was Pluto by Clyde Tombaugh in 1930 (later numbered 134,340; see numbering convention described below). This discovery confirmed early ideas concerning the existence of solar system objects beyond the orbit of Neptune. In fact just a few months after Pluto's discovery, Frederick Leonard (1930) wrote in a popular article:

Now that a body of the evident dimensions and mass of Pluto has been revealed, is there any reason to suppose that there are not other, probably similarly constituted, members revolving around the Sun outside the orbit of Neptune?... As a matter of fact, astronomers have recognized for more than a century that this system is composed successively of the families of the terrestrial planets, the minor planets, and the giant planets. Is it not likely that in Pluto there has come to light the first of a series of ultra-Neptunian bodies, the remaining members of which still await discovery but which are destined eventually to be detected?

Later on, in the years 1943 and 1950, Kenneth Edgeworth and Gerard Kuiper hypothesized the existence of small bodies beyond Neptune and Pluto. A more conclusive study by Fernández and Ip in 1982 argued for the existence of a source of short-period comets close to the ecliptic plane and beyond the known planetary orbits.

Even if many researchers hypothesized the existence of such a population, only after more than 60 years, in 1992, did Jewitt and Luu discovered a second transneptunian object 1992 QB₁ (now numbered 15,760; Jewitt and Luu 1993), if we do not take into consideration the discovery of

Pluto's moon Charon in 1978 (because at that time, it was considered a satellite of the ninth planet). This was an epochal astronomical discovery and within 2–3 years more than 100 distant objects were discovered. Determining their orbits was in general difficult because of their faintness and the necessity to observe them for several months. After discovery, these objects receive a provisional designation as asteroids (year of discovery followed by letters and number for the order of discovery). Only when the orbit is well known, do they receive a number and a name. As activity is not visible during the discovery and observations, their number follows the order number of asteroids rather than comets.

More than 3000 transneptunian objects with well-constrained orbits are known up to date, showing a variety of sizes, orbits, and surface characteristics. Because of their distance and their faintness, some transneptunians were lost after discovery. Satellites have been detected for a large fraction of these objects using optical methods of high-resolution imaging. Most of these satellites have been found with the Hubble Space Telescope (Noll et al. 2008; Grundy et al. 2011). Recently, stellar occultations by Centaurs and TNOs permit the discovery of the first ring systems not circling a giant planet: a double ring around the Centaur Chariklo (Braga-Ribas et al. 2014), a single ring around the dwarf planet Haumea (Ortiz et al. 2017), and rings are suspected on other bodies (Ortiz et al. 2015).

The largest TNOs, Pluto, Eris, Makemake and Haumea, have been classified as dwarf planets by the International Astronomical Union in 2006.

Dynamical Classification

The population has been classified (Gladman et al. 2008) into several groups, following their distance from the Sun and their orbital characteristics: (1) classical objects, (2) resonant objects, (3) scattered disk, and (4) detached objects (Fig. 1). The first two groups are also known as the Kuiper Belt, containing objects with an average distance from the Sun between 30 and 55 AU with almost circular orbits and small inclinations.

Kuiper Belt, Fig. 1 The diagram illustrates the distribution of transneptunian objects (resonant, classical, scattered disk, and detached objects) at different semimajor axes (a), eccentricities (e), and inclinations (i). (Provided by A. Morbidelli)

Resonant objects are trapped in mean-motion resonances with Neptune and that dynamical configuration provides them a dynamical stability. Although more than 20 resonances exist, the 3:2 mean-motion resonance with Neptune ($a = 39.4$ AU), which hosts Pluto, is the most densely populated, and objects trapped into this resonance are called plutinos. The origin of these resonant objects is closely related to Neptune's migration: indeed, while Neptune was migrating outward, objects that followed the outward migration of Neptune were swept and captured in a mean-motion resonance.

Classical objects are those having a low eccentricity and moderate inclination. Several authors refer to two distinct populations in the classical belt based on orbital inclination: dynamically "hot" (high inclination, $>5^\circ$) objects and dynamically "cold" (low inclination, $<5^\circ$) objects. Numerical simulation by Gomez (2003) showed that the hot population could find its origin in the migration of Neptune, which scattered the

planetesimals originally formed inside about 30 AU. The current classical belt would hence be the superposition of these bodies with the local population (cold objects), believed to have formed in situ beyond 30 AU. The so-called Kuiper Belt has a characteristic edge at about 48 AU, near the location of the 2:1 mean-motion resonance. It is not clear how this edge formed and if it is real (or due to an observational bias effect). The position of this edge might depend on Neptune's migration (Levinson and Morbidelli 2003) or a close stellar passage as suggested by Ida et al. (2000).

Scattered disk objects (SDOs) or scattered objects are considered those that have orbits with large eccentricities and perihelion distances near Neptune's location. Several objects previously classified as SDOs are in fact resonant. The majority of SDOs have unstable orbits and are perturbed by the close encounters with Neptune, but some might have survived since the origin of the solar system (Duncan and Levison 1997). Part of them

might have been injected in their present orbits from other regions by perturbation produced by stars passing nearby our solar system (Levinson and Morbidelli 2003) or by sweeping resonances during the planetary migration phases (Malhotra 1995).

Detached objects are those with orbits having large eccentricities ($e > 0.24$) and with large perihelion distances out of Neptune's influence. They have very long lifetimes under the influence of other planetary perturbations. Their origin is not well understood and several scenarios exist to explain their formation. The best example of this category is (90377) Sedna, which has a semimajor axis of 501 AU, with perihelion and aphelion distances at 76 and 927 AU, respectively. The most distant TNO known today is 2017 MB₇ with perihelion at 4.46 AU and aphelion at 2906 AU. It is probable that many more distant objects are waiting to be discovered. A large population in the distant region is predicted, but no surveys for fainter objects have yet succeeded in detecting such distant objects.

During the planetary migration in our solar system, most of the mass of the Kuiper belt was lost, and part of the bodies ejected outside feeding the Oort cloud. Later, the migration of bodies in the opposite direction, that is, from the Oort cloud to the Kuiper belt region, could have taken place because of the gravitational perturbations produced by supernovae explosion, galactic tide, or nearby passing stars.

Another group of objects with similar physical characteristics is called *Centaurs*, which orbit in the region between Jupiter and Neptune and interact strongly with all the giant planets. Planetary perturbations and mutual collisions in the Kuiper Belt are probably responsible for the ejection of objects onto Centaur orbits. Because Centaurs cross the orbits of the outer planets, they are dynamically unstable with a short lifetime (10^6 – 10^7 years), after which they can be ejected from the solar system, impact the giant planets, or evolve into Jupiter-family ► [comets](#) (JFCs) or near-Earth objects (NEOs). Centaurs are widely believed to come from the transneptunian region and to be scattered into their present orbits by gravitational instabilities and

collisions. Hence, like the transneptunian objects, Centaurs accreted at low temperature and large solar distances and must still contain a relatively pristine material.

Basic Methodology

The availability of very large telescopes, both ground based (≥ 8 m) and orbiting the Earth (Hubble, Spitzer, and Herschel), has enabled observational studies of the physical properties of a significant number of objects, but the physical properties of smaller transneptunian objects remain still poorly known. Obtaining this information for the whole population is still a big challenge. In situ observations by the NASA New-Horizon mission permitted a detailed investigation of the dwarf planet Pluto and of its satellite system, and the first study of a relatively small sized TNO, Arrokoth.

The diameter of the TNOs can be estimated from their absolute magnitude, but only if their albedo is known, which can be determined when both the reflected light and the thermal radiation at long wavelengths are measured (the so-called radiometric technique). These objects are very cold (30–50 K); their thermal radiation is very weak because of their distance from the Sun, and their blackbody peak is near 70–100 μm , that is in a wavelength region not easily accessible from ground-based observatories because of the telluric atmosphere's low transmission. Therefore, observations from space telescopes are required to study the size of this population at a statistically significant level. In the past 15 years, the Spitzer, WISE, and Herschel infrared space telescopes permitted a big step forward in the determination of the transneptunian population size, albedo, and thermal properties. The Spitzer Space Telescope has been used to observe approximately 50 Centaurs and transneptunian objects (Stansberry et al. 2008), and using both thermal emission and ground-based measurements of the visible radiation, their dimensions have been determined with a precision of 10–20%. Wise observed about 50 Centaurs and SDO. Finally Herschel, whose instruments cover the peak of the TNOs thermal

emission, investigated 170 TNOs and Centaurs (Müller et al. 2020).

The most striking observation is the huge variation of the albedo value across the TNO population, which includes both extremely dark surfaces with geometric albedo of 2–3% and high reflective bodies reaching an albedo of 96% in the case of Eris. Very high albedo are however unusual and associated to few TNOs, including the volatile-rich dwarf planets and the members of Haumea family, all showing at their surfaces exposures of water ice. Excluding these peculiar bodies, the TNOs surfaces are quite dark with an average albedo of $9.9 \pm 0.5\%$.

The size of known TNOs ranges from a few tenths of km to 2376 km for the dwarf planet Pluto. An observational bias affects the smaller TNOs, because their detection and precise characterization is extremely challenging. The smallest TNOs measured is Arrokoth, flew-by in

2019 by the New-Horizon mission, a contact binary object having an equivalent diameter of 18 km (Stern et al. 2018). The largest TNOs is Pluto, followed by Eris which is very similar in size (2326 km), Haumea (elongated body with equivalent diameter of 1595 km), Makemake (1440 km), GongGong (1230 km) and ~1000 km bodies like Quaoar, Orcus, Sedna, and Salacia (see Fig. 2, and Barucci et al. 2021).

Besides radiometry, diameters can be measured very precisely by the stellar occultation technique, measuring the duration of a star flux occultation when a TNO or a Centaur pass in front of it. This technique allowed the precise size estimation for about 15 TNOs and Centaurs, and the discovery of ring systems around Haumea and Chariklo. This technique is powerful but limited by the fact that it requires high accuracy both in the TNOs ephemeris and in the stellar catalogs.

K

Kuiper Belt, Fig. 2 Picture of the biggest transneptunian objects that are reported in scale with their estimated sizes, satellites, and rings. (© NASA Courtesy)

The TNOs’ density can be estimated only when satellites are detected, and consequently, the mass of the primary is available. When the orbital period and distance of the satellites can be determined, the mass of the primary body can be calculated from Kepler’s third law, and the mass of the satellite can also be estimated from the magnitude of the systems’ components. The mean density reflects the internal composition, particularly the relative fraction of ices, silicates, and metals, as well as the internal structure. Density has been computed for 25 binary systems, and it spans a wide range, from ~ 0.3 to nearly 2.5 g/cm^3 .

Most of the TNOs smaller than 400 km have density less than 1 g cm^{-3} , implying a small rock to ice ratio and a high porosity to varying degrees. The lowest measured density ($\sim 0.3 \text{ g cm}^{-3}$) is for Altjira and Typhon, implying that about 50–70% of the interior of these bodies consists of void space. TNOs larger than ~ 750 km in diameter have density greater than 1 g/cm^3 indicating a larger rock to ice ratio and/or less porosity. The highest density has been measured for the dwarf planet Eris (2.5 g/cm^3 , Sicardy et al. 2011), followed by Pluto, Haumea, and Makemake (density of $1.7\text{--}1.85 \text{ g/cm}^3$), suggesting a large rock to ice ratio for the dwarf planets. Table 1 shows some physical characteristics of these objects.

The current uncertainty in the size distribution of the TNOs does not allow us to define the total mass of the population. Current estimation ranges from 0.01 to a few times $0.1 M_{\text{solar}}$.

A TNO’s rotational period can be determined by measuring its light curve. The few dozen known rotational periods span from a few hours to several days with a peak around 7.7 h, which appears to be significantly slower than the main-belt asteroids of similar size. From the rotational properties, it is also possible to extract information on the collisional history, since the current spin properties are supposed to have been strongly affected by the mutual collisions experienced by these bodies. On the basis of considerations of the rotational stability, the density can be also constrained. Assuming that the amplitudes of the observed light curve are due to the body’s shape, with negligible albedo variations on the surface, an estimation of a lower limit to the axis ratio a/b on the hypothesis of an ellipsoid shape can be also deduced. Smaller objects appear to be more elongated.

The statistics on binary TNOs can provide models of their formation. Angular moment and relative sizes of most binaries are consistent with formation by dynamical capture. The small satellites of the largest objects, in contrast, more likely result from collisions. More than 70 trans-neptunian binaries are known, but triple or multiple systems have also been detected.

Kuiper Belt, Table 1 Properties of the largest TNOs

	Pluto	Eris	Makemake	Haumea	Sedna	Quaoar	Orcus
Diameter (km)	2376 ± 2	2326 ± 12	1440 ± 9	1595 ± 11	995 ± 80	1110 ± 5	958 ± 23

Composition

While spectroscopy provides more details for surface composition investigation, photometry has been the most extensively used technique to explore the surface properties of these remote objects, since most TNOs are extremely faint. Many different photometric observational campaigns have been performed, particularly in the visible region, which provided data for a large number of objects.

About 200 objects have been observed with photometric surveys, revealing surprising color diversity; the TNOs exhibit a large range of surface optical colors. A large number of transneptunian objects have surface colors much redder than any other solar system bodies. Statistical analyses have been used in researching a wide range of possible correlations between optical colors and orbital parameters. The visible and near-infrared color correlation indicates that a single coloring agent is responsible for the wavelength dependence. In particular, there is a well-confirmed correlation (Doressoundiram et al. 2008) between color and orbit inclination. Highly inclined classical objects have diverse colors ranging from gray to red and have large sizes, while low-inclination classical objects are generally smaller and mostly very red. This cluster of “cold” (low-eccentricity, low-inclination) classical objects composed of smaller sizes is supposed to be primordial.

Results on the photometry of binary TNOs observed with the Hubble Space Telescope demonstrate a very strong correlation between primary and satellite colors, concluding that the colors of binaries as a group are indistinguishable from that of the larger population of apparently single transneptunian objects. The color of binaries or single objects is one characteristic signature of surface compositional differences set in the solar nebula.

Multicolor broadband photometry can provide only limited constraints on the surface composition of the population. In fact, colors can be influenced not only by composition, but also by scattering effects in particulate regolith and by viewing geometry. Colors cannot, in general, be used to determine composition, but they can be

used to classify objects into groups. A taxonomy based on color indices (B-V, V-R, V-I, V-J, V-H, and V-K) has been obtained (Barucci et al. 2005) identifying four groups of objects with homogeneous color content: BB, BR, IR, and RR. The group BB contains objects with neutral colors and RR those with very red colors (the reddest among the solar system objects), while the two others have an intermediate behavior. The physical significance of color diversity is still unclear, though it is reasonable to assume that the different colors reflect intrinsically different compositions or compositions that differ due to different evolutionary histories. The trend from neutral (BB) to very red (RR) groups indicates the possible sequence of alteration processes (collisions, resurfacing, craters, UV and/or energetic particle bombardment, etc.), and each group could represent an evolutionary stage of the population, and its number density gives an indication of the duration of each phase representing the effects of different alteration processes. Cosmic-ray bombardment will be the cause for an exposed surface to become redder, and impacts excavating “fresh material” will cause differently colored surfaces. These as well as other evolutionary processes (e.g., outgassing, surface gardening, atmospheric interaction, etc.) can also account for the observed differences.

The Centaurs seem to have a different distribution of colors. The available data suggest that the Centaurs’ colors may have a bimodal distribution, while the TNOs do not. This has been explained by past or present sublimation activity. In fact, when these objects pass closer to the Sun, they can develop an active coma.

The most detailed information on composition can be acquired only from spectroscopic observations, especially covering the wavelength range between 0.4 and 2.4 μm . This wavelength range provides the most sensitive technique to characterize from the ground the major mineral phases and ices present on transneptunian objects (Fig. 3). Silicate minerals like feldspar, carbonaceous assemblages, organics, and water-bearing minerals have diagnostic spectral features in the visible and near-infrared spectral regions. In the near-infrared region, there are also signatures

Kuiper Belt,

Fig. 3 Visible and near-infrared spectra of some TNOs (Sedna, Eris, and Orcus) and a Centaur Asbolus. The four objects have spectra with different behaviors (from flat to very red spectra), different absorption bands, and different signal-to-noise ratios

from ices and hydrocarbons. Weakly active Centaurs or TNOs could also show fluorescent gaseous emission bands.

Most of the known transneptunian objects are too faint for spectroscopic observations, even with the world's largest telescopes, and so far, only the brightest bodies have been observed by spectroscopy. The exposure time required is generally long, and as the objects rotate around their principal axis, the resulting spectra often contain information coming from both sides of the object.

Visible spectra are mostly featureless, showing large variations of the spectral slope, thus confirming the wide range of colors from neutral to very red. The visible wavelength is important to constrain models and to infer information on the composition, particularly for the ultrared objects. The ultrared slope is assumed to indicate the presence of organic material on the surface, as in the case of the Centaurs Nessus and Pholus (the reddest objects known up to now). A few objects show signatures which are very similar to those due to water-altered minerals found in some main-belt asteroids and meteorites (Barucci et al. 2008a). How an aqueous alteration process could have occurred at such low temperatures far from the Sun is not yet well understood, but it

cannot be excluded that hydrated minerals could have been formed directly in the early solar nebula; in fact, hydrous silicates have been detected in interplanetary dust particles (IDPs) and in [micrometeorites](#).

The near infrared (1–2.4 μm wavelength) is the most diagnostic region to determine the presence of ices. Signatures of water ice, methane, and methanol can be easily detected if the spectra are of good quality. In a few cases, some data at longer wavelengths have been obtained with the far-IR space telescope Spitzer. To investigate the composition, radiative transfer models have been used to interpret the features and the spectral behavior using intimate or geographical mixtures of organics, silicate minerals, carbonaceous assemblages, ices, and/or hydrocarbons. The red slopes are in general well reproduced supposing the presence of organic compounds on the surface like kerogen (complex dark organic compound) and tholins (synthetic macromolecules produced by irradiation of gaseous mixtures).

The results given by the spectral modeling have to be considered as only indicative. In fact, much of the information obtained from spectral modeling is nonunique, especially if the necessary constraints are not well established ([albedo](#), signatures with high-sensitivity detections of

fainter components, etc.). The details on fractional coverage of different materials and even the presence of these materials are easily influenced by choices of model parameters. Nevertheless, the modeling can be used to pick out broad variations in TNO spectra.

Key Research Findings

In recent years, about 80 objects including Centaurs have been spectroscopically observed and analyzed. Following their spectral characterization, four principal groups can be identified.

Water Ice Group

Water ice should be the main component of transneptunian objects, and many have spectra showing moderate to deep absorptions due to water ice. Most spectra with high signal-to-noise (S/N) show the presence of a feature at 1.65 μm characteristics of crystalline water ice. It is still a matter of debate whether water ice was amorphous or crystalline in the protosolar nebula. While crystalline water ice is neither expected at these low temperatures nor should be stable against cosmic-ray and UV bombardment, crystalline water ice appears to be ubiquitous in the outer solar system, from the icy satellites of the giant planets to TNOs. The presence of crystalline water ice implies that ice has been heated to temperatures above 100/110 K. This heating could have occurred by impacts or generated in the deep interiors and the ice then been emplaced onto the surface. The quality of most spectra is too poor to distinguish between amorphous or crystalline water ice. Nonetheless, when trying to model the spectra, the best fit model is usually obtained when using a combination of the two water ice states.

Methane Group

The largest TNOs – Eris, Pluto, Sedna, and Makemake – display spectra dominated by methane absorption, some objects showing spectra of methane dissolved in nitrogen. Pluto and probably Sedna and Eris share these properties, together with Neptune's satellite Triton (supposed to be a

transneptunian object captured by Neptune). Methane is present in these large objects because their gravity is high enough to retain such a volatile component, but in smaller quantity, methane may be present also on smaller objects. A small amount of ethane (by-product of methane ice irradiation) has also been detected on Quaoar.

Methanol Group

Some objects – Pholus (55638) 2002 VE₉₅ and possibly Bienor – show spectra with methanol. Many objects have a low signal-to-noise ratio, especially in the near-infrared region around 2.2 μm , but many objects show a decreasing slope after 2.2 μm implying a possible presence of methanol or similar organic molecules.

Featureless Spectra Group

Many objects have featureless spectra in the near infrared, with a wide range of colors. Obviously, many spectra are featureless when observed at low S/N, but many have sufficient S/N spectra to rule out the signature due to water ice. These objects could be mantled by a surface rich in organics or carbon. As all these objects are supposed to be composed of ices, irradiation processes have to be responsible for these properties. Laboratory experiments have showed that irradiated ices become redder with increasing irradiation. Molecules progressively lose their hydrogen atoms, which results in a polymerization of the surface layer and the formation of a crust.

Ammonia or ammonia hydrate has been detected in the spectra of a few objects (Charon, Orcus). A firm detection of ammonia would have important implications on the composition of the primitive solar nebula in the region at low density, far from the Sun.

The Largest Objects

The dynamical and physical characteristics of the largest transneptunian objects are summarized in Table 1.

Pluto

Pluto is the largest transneptunian extensively investigated from ground-based telescope and

in situ thanks to New-Horizon mission. In fact, its high albedo and its position at perihelion make it the brightest object of the transneptunian population, and for this reason, it was the first discovered and has been heavily observed. Its surface shows both compositional heterogeneity and geological diversity (Stern et al. 2018), including smooth volatile-rich planitia, craters, troughs, and scarps produced by extensional tectonics, polygonal networks associated to convection cells, and mountains as high as 6 km supported by a water ice bedrock. Pluto retains an atmosphere mainly composed of N_2 , with lesser amounts of CH_4 and CO , and showing seasonal variations.

Pluto composition is dominated by methane, nitrogen, and lesser amounts of CO ice and minor hydrocarbon species. The methane is present in both pure and diluted states, and ethane is also present in its surface together with relatively dark and spectrally red regions with featureless spectra. These last reddish units may be the product of the irradiation of ices native to Pluto's surface, or generated from cryovolcanic activity, or result from the deposition of the atmospheric haze over geological timescales. The New-Horizon mission revealed that Pluto has been and still is geologically active, and its internal structure should be differentiated including a rocky core, an icy mantle, and a crust dominated by volatile material, which may survive as ice due to the low temperature, ranging between 30 and 60 K.

Pluto is surrounded by five known satellites (Charon, Styx, Nix, Kerberos, and Hydra). The formation of these satellites could be as a consequence of a grazing collision between the proto-Pluto and Charon. Charon is the biggest with a diameter of 1212 km and its mass is about a tenth of that of Pluto. It is not massive enough to retain an atmosphere. Its surface shows compositional variations and, conversely to the methane-rich Pluto, it is dominated by water ice. The lack of craters on its surface suggests that it may have been geologically active. The other satellites of Pluto are relatively small, with size ranging from 10 to 12 km for Styx and Kerberos, to about 36 km for Nix and Hydra (Stern et al. 2018).

Eris

Eris has a highly eccentric orbit, with a perihelion at 38.4 AU, typical for scattered objects, and an aphelion at 97.5 AU. Its orbital period is about 560 years. It is the most massive object $((1.67 \pm 0.02) \times 10^{22} \text{ kg})$ of the TNO population and it has one known satellite, Dysnomia, that is 500 times fainter than Eris. The spectrum is very similar to that of Pluto even if the visible part is less red than that of Pluto. No variation has been seen on Eris to an upper limit of 0.05 mag. The visible and near-infrared spectra are dominated by absorption from methane. As shown by Merlin et al. (2009), the near-infrared spectrum shows no evidence for shifts of the methane absorption wavelength, while the visible part of the spectrum shows small shifts, implying that methane is dissolved in nitrogen. These observations suggest a stratification, with a layer of diluted methane ice between two layers of pure methane ice. The possibility to have depleted nitrogen in the deepest layers after sublimation processes that enrich adjacent layers during condensation processes can be also suggested. Eris seems to be covered by more pure methane ice than Pluto and Triton. The amount of nitrogen on Eris' surface is probably smaller and less important than on the surfaces of the latter objects. The high albedo and the lack of rotation are consistent with a surface dominated by seasonal atmospheric cycling.

Makemake

Makemake belongs to the classical population. It has an orbital period of nearly 306 years, more than Pluto's 248 years and Haumea's 283 years. It is the brightest TNO after Pluto and has a surface dominated by methane. The methane absorption features on its surface spectrum are deeper and broader than those on the other objects. A signature of ethane is also present. Ethane is one of the expected products from dissociation of both gaseous and solid-state methane. For its known characteristics, Makemake can be a transition between the larger-surface-volatile-rich objects and the smaller-surface-volatile-depleted objects.

A relatively large satellite of about 260 km in size was discovered orbiting around Makemake, permitting to reconcile discrepancy in the thermal fluxes recorded by Spitzer and Herschel space observations.

Haumea

(136108) Haumea is a unique dwarf planet boasting a system of satellites, rings, and a family of objects all with almost pure water ice surfaces. Haumea has a typical orbit for the classical dynamical group, with an orbital period of 283 years and a perihelion at 35 AU. It has an unusual light curve, with large amplitude and small rotational period (3.92 h) implying an ellipsoid shape. Star occultation by Haumea permits to determine its size and its very elongated shape and to discover a ring of about 70 km width located 2300 km from the center of the dwarf planet (Ortiz et al., 2017). Haumea is very elongated, its shape corresponds to a $2320 \text{ km} \times 1705 \text{ km} \times 1025 \text{ km}$ ellipsoid. Its equivalent diameter, that is that of a sphere having the same volume, is 1595 km. The near-infrared spectroscopy reveals the deepest water ice absorption found in these objects, with surface composition similar to the surface of Pluto's moon Charon. Its characteristics and those of its two satellites (Namaka and Hi'iake) all point to a collisional origin for the system (Brown et al. 2007). A large near-infrared survey showed that a number of TNOs having deep water ice absorption are all dynamically clustered near the dynamical position of Haumea, representing a dynamical family. It is probable that the objects of this family, the first family detected in the TNO population, are the collisional fragments of a giant impact on the proto-Haumea.

Sedna

Sedna is one of the most remote objects with a perihelion distance at 76 AU, an aphelion distance at 927 AU, and an orbital period of about 11,000 years. It is also one of the reddest trans-neptunian objects known. Methane and possibly nitrogen seem to be present on the surface of this object, and a similarity with Triton has been proposed, which could indicate that these two objects

originated in the same zone. This would better account for the origin of Sedna and would support a capture hypothesis for Triton. During its perihelion passage, Sedna may have a temporary N_2 atmosphere whose properties depend upon the rotational period.

Quaoar

Quaoar is a 1000 km size body belonging to the classical dynamical group. The rotational period is approximately 8.84 h, and it has one known satellite (Weywot, about 80 km in size). The best compositional model obtained so far (Barucci et al. 2015) reported a surface made of crystalline water ice, methane, as well as ethane, nitrogen, organic materials, and possibly ammonia water. The presence of high volatile material such as ammonia water and nitrogen suggests that the surface of Quaoar may be relatively young and shaped by an efficient renewal mechanism.

Orcus

Orcus is in the 3:2 resonance with Neptune with an orbit similarly to that of Pluto. It is a 1000 km size body. A relatively big satellite (diameter of $276 \pm 17 \text{ km}$) has been discovered and named Vanth. The derived density is $1.53 \pm 0.15 \text{ g cm}^{-3}$ (Fornasier et al. 2013), the lowest known value among the large TNOs listed above. A possible rotational period of about 10 h has been estimated. Crystalline water ice and possibly ammonia (Barucci et al. 2008b) have been found on its surface from spectroscopic observations. The existence of such ices may indicate a renewal mechanism on the surface such as geological activity.

Physical Processes

The TNO population is considered to contain the most pristine objects in the solar system, but over the 4.5 Gy of the solar system life, they have experienced various modifying processes.

The structure and the chemistry of the surface of these objects are affected by bombardment by cosmic ray and solar wind ions and/or micrometeorites, with the result that the molecular complexes are structurally changed and the molecular

compositions of ice and minerals are altered over time. Laboratory experiments on a variety of appropriate materials irradiated by energetic particles, simulating the space environment, show molecular transformation that leads to the production of different components. Energetic particles dissipate their energy in a complicated cascade of interactions that results in the production of molecules that were not present in the initial composition. Laboratory experiment shows the formation of an irradiation mantle, breaking bonds in the ice molecules to allow the formation of radicals, leading to the escape of hydrogen and the formation of a carbon-rich layer with low albedo. This can easily mask the presence of volatiles. The depth to which material can be damaged is a function of the particle energy.

Hudson et al. (2008) reported the estimation of the irradiation at different distances from the Sun. TNOs orbiting in the classical belt (40–50 AU) received lower irradiation than those orbiting beyond the terminator shock (beyond about 85 AU); the latter have upper layers more deeply affected by irradiation-induced chemistry, forming a crust rich in carbon. The formed crust hides the real composition of these objects, and complex organic materials called “tholins” (produced by spark discharge in low-pressure gases) or “kerogen” (found in terrestrial oil shales) are often used as analogues for interpreting the spectra of the surface.

It is clear that collisions have played an important role in the evolution of this population. The consequence of collisions is not only the alteration of the surface properties but also the modification of the internal structure of the targets. Collisions are relevant to both small and large objects. One example is Charon, a moon of Pluto, but completely different in composition from Pluto; it has been modeled to have formed from a disk of debris ejected during the collision of Pluto with a body of almost equal size, in a process similar to that of the formation of Earth’s Moon. It has been suggested that the collisional family associated with Haumea originated from a parent body having a high-density rocky core and a low-density icy mantle that suffered a giant collision, ejecting a large fraction of its mantle into space. In fact, some objects with similar spectral characteristics

(deep H₂O ice band and neutral color) have been identified to be clustered around Haumea.

The internal structure of TNOs can also display a great diversity. The detection of crystalline H₂O ice or ammonia ice on the surfaces raises the question of internal activity. Laboratory experiments on water ice irradiation at the same conditions as TNOs indicate that crystalline water ice on the surface should be completely amorphized by irradiation in about 10⁷ years; in fact, crystalline water ice is neither expected at these very low temperatures nor should be stable against cosmic-ray and UV bombardment. Both internal (cryovolcanism) and external (micrometeoritic or larger impacts) surface renewal mechanisms have been considered to account for the presence of crystalline water on the surface of these objects, even if the understanding of the physics of the crystalline/amorphous phase transition is not clear. Laboratory experiments show the same behavior for the ammonia hydrates, which are easily destroyed by energetic radiation.

Studies of the early evolution of transneptunian objects concluded that some bodies (depending on the orbit and size) should have lost all volatile ices, such as water ice crystallized because of the heat generated by accretion, short-lived radiogenic elements, and differentiation (McKinnon et al. 2008). The presence of some ices on the large TNOs indicates that other mechanisms (not only space weathering and collisions) could be the cause of the surface properties. Some internal geological activities, for example, have been proposed as explanation for the surface characteristics of Orcus and Quaoar.

Models of the interiors of TNOs show that cryovolcanism, which is considered the most probable mechanism to explain geological activity on some satellites of the outer planets, may be possible on the bigger transneptunian objects (diameter >1000 km). Outgassing from the interior is another important evolution process not only because of the high volatile content but also due to the possible high porosity of these objects. In fact, the porosity can increase the conductivity of volatiles to the surface and the size of the reservoir that supports the escaping atmosphere or coma. The high albedos and the detection of

volatiles on the surfaces on some transneptunians suggest a possible presence of an atmosphere, even as a transient phenomenon. Pluto has a seasonal atmosphere. The requirement for atmospheric formation on these low-gravity objects requires the presence of gases or sublimating/evaporating materials on the surface, and this implies a resupply mechanism such as internal activity or impactors. The detection of surface volatiles and high albedos on some TNOs thus indicates the possible existence of at least transient (e.g., seasonal) atmospheres on some of these objects. The definitive evidence for atmospheres can only come from occultations or direct spectroscopic detection with spacecraft.

Future Directions

Many ongoing and future surveys [the Panoramic Survey Telescope and Rapid Response System (Pan-STARRS) and the Large Synoptic Survey Telescope (LSST)] are and will cover the transneptunian region, allowing the discovery of many more objects, with orbital and physical characterization. The population of small and very faint objects can be discovered only through occultations of background objects; in fact, this method could investigate down to the sub kilometer-sized population of the TNO size distribution, as well as the outer region of the Kuiper Belt. This technique can be applied to many new objects thanks to the high precision stellar catalogues produced by GAIA mission. Stellar occultations observed from the ground will be also the most powerful tool available to determine the shape, size, and the presence of an atmosphere for the larger objects with well-known precise orbits. In the future, 30–40 m size telescopes like the Giant Magellan Telescope (GMT), the Thirty Meter Telescope (TMT), and the Extremely Large Telescope (ELT) will allow a better characterization of many of these objects, extending the investigation also toward fainter TNOs. Finally, the James Webb Space Telescope, expected to be launched in 2021, will permit a big step forward in the characterization of the surface properties of these distant solar system objects.

L

L-Amino Acids

Jeffrey Bada
Scripps Institution of Oceanography, La Jolla,
CA, USA

Definition

L-amino acids are the only enantiomer of the amino acids with a chiral carbon atom encoded by genetic molecules into the proteins of terrestrial organisms. There are some D-amino acids found in the proteins of living organisms, but these are added by post-translational modification reactions or incorporated through nonribosomal synthesis.

L1544

Charlotte Vastel
Institut pour la Recherche en Astrophysique et
Planétologie, Toulouse, France

Keywords

Chemistry · Molecules · Interstellar medium ·
Complex organic species · IRAM telescopes ·
Herschel Space Observatory

Definition

L1544 is a prototypical prestellar core which represents the earliest phase in the process of star and planet formation. This core is relatively isolated in the Taurus molecular complex (distance ~ 140 parsecs, coordinates: $\text{ra}(2000) = 05^{\text{h}} 04^{\text{m}} 17.21^{\text{s}}$, $\text{dec}(2000) = +25^{\circ} 10' 42.8''$) and has been extensively observed by single-dish and interferometer spectroscopy. L1544 is characterized by a low temperature ($T \sim 7$ K) and high density ($n(\text{H}_2) > 10^6 \text{ cm}^{-3}$) in its center. The temperature increases and the density decreases as a function of radius. L1544 is contracting making it the perfect example of the evolution of a starless core towards the protostar phase.

Overview

Soon after the discovery of radio emission from interstellar molecules, L1544 was recognized as a strong source of line emission and absorption (Dieter 1973; Minn and Greenberg 1973; Cheung et al. 1973), and since then, it has been a target for the search for rare molecular species. Beichman et al. (1986) did not find any infrared IRAS point source associated with L1544 that fulfils their ► [protostar](#) selection criteria and categorized this core as “starless.” L1544 has then been classified as a prestellar core, which is a subset of starless cores that are gravitationally bound and hence expected to participate in the star-formation process (Ward-Thompson et al. 1994). Detailed studies of the L1544 prototypical prestellar core have found central temperatures of only 7 K (Crapsi et al. 2007). An extreme molecular deuteration is a major characteristic of pre-stellar cores where ► [Carbon Monoxide](#) (CO) is depleted from the gas phase which leads to the preferential reactions between the H_3^+ ion with HD, feeding the ► [deuterium](#) of the latter ion, and distributing deuterium in the gas-phase and on the grain surfaces. A high deuterium fractionation has been detected in L1544 (e.g., Caselli et al. 1999; Crapsi et al. 2005; Bizzocchi et al. 2014) in which H_2D^+ has been detected (Caselli et al. 2003). The central 7000 au is called the deuteration zone, where the freeze-out of abundant neutrals such as CO and O, the main destruction partners of the H_3^+ isotopologues, favor the formation of deuterated molecules. The outer ring (7000–30,000 au) is called the dark-cloud zone (Caselli and Ceccarelli 2012), where carbon is mostly locked in CO, gas-phase chemistry is regulated by ion-molecule reactions and deuterium fractionation is reduced.

The ► [Herschel-HIFI](#) instrument detected for the first time ► [water](#) in a prestellar core (Caselli et al. 2012) with an inverse P-Cygni profile, characteristic of gravitational contraction in the inner regions.

Maps at the IRAM-30m telescope revealed a chemical differentiation in this core. For example ► [methanol](#) (CH_3OH) shows an asymmetric

structure (Bizzocchi et al. 2014) in the northern part of the core, consistent with central depletion (CH_3OH is produced on the surface of ► [dust grains](#) by successive hydrogenation of CO). On the contrary, the $\text{c-C}_3\text{H}_2$ distribution peaks in the southern part of the core, where photochemistry maintains more C atoms in the gas phase (Spezzano et al. 2016). Several ► [complex organic molecules](#) (COMs) (e.g., acetaldehyde, dimethyl ether, formic acid, and methyl formate, propyne) have been detected at the dust peak (Vastel et al. 2014) and methanol peak (Jiménez-Serra et al. 2016), likely related to methanol, as well as CH_3O , a possible product of methanol photodissociation (Bertin et al. 2016). A nonthermal desorption mechanism is possibly responsible for the observed emission of methanol and COMs from the external layer of the core. Many species (CH_2CN , HCNH^+ and HC_3NH^+) have recently been detected for the first time in a prestellar core (Vastel et al. 2015; Quénard et al. 2017) and an extensive study has been performed (Vastel et al. 2018) on the sulfur chemistry. Sulfur is likely depleted in the cold and dense phases of the interstellar medium, although there is no strong evidence of sulfur in the observations of the ice mantles so far.

The large-scale properties of the L1544 cloud have been studied in CO (Tafalla et al. 1998) and shows that L1544 is part of an elongated filament. More recently, the large-scale Herschel dust continuum map shows the interaction between two almost perpendicular ► [Interstellar Filaments](#), with the L1544 methanol peak found at the intersection (Punanova et al. 2018).

Definition

Laboratory astrophysics is a multidisciplinary field that explores astrophysical phenomena and supports the interpretation of astronomical observations, solar-system in situ measurements, and extraterrestrial sample analysis through the use of laboratory experiments, theoretical calculations, and numerical simulations. Laboratory astrophysics provides fundamental data for the modeling of astrophysical and planetary environments and processes.

Overview

Primarily driven by ground-based observations, space missions, and meteoritic material studies, the research areas covered include atomic and

molecular astrophysics, physics and chemistry of condensed matter, plasma astrophysics, fluid dynamics, and nuclear and particle astrophysics. The tools range from quantum chemical calculations, to large-scale facilities such as synchrotrons, ion accelerators, and ultrahigh-intensity lasers. Laboratory astrophysics relies on the collaboration of experts from many fields: astronomers, physicists, chemists, geophysicists... (Savin et al. 2012).

In the context of astrobiology, one of the first aims of laboratory astrophysics is to understand the nature, origin, evolution, and fate of cosmic matter – dust, ice, and molecules – observed in space, in environments often characterized by harsh physical conditions and submitted to strong UV irradiation, cosmic rays, impact of electrons, or shock waves (Sandford et al. 2020). Despite these extreme conditions, a very rich chemistry is observed in interstellar clouds leading to a high molecular complexity. Emission or absorption spectroscopic studies of solids and molecules (from the X-ray to the millimeter domain) play a key role in the identification of the various components. They are complemented by in-depth investigation of gas-phase mechanisms, solid-state chemistry, and gas/solid interactions at the molecular level. The understanding of the physical and chemical processes at play requires the development of state-of-the-art laboratory experiments (dedicated ultrahigh vacuum chambers, low-temperature flow reactors, excitation sources...) to identify precise reaction pathways, determine branching into various reaction exit channels, measure quantitative reaction kinetics, or photo-processing cross sections. Some of these devices are installed on large infrastructures such as heavy ion accelerators or synchrotrons.

One of the major issues is to understand how the molecular complexity reached in the ISM is transmitted along the lifecycle of astronomical objects from interstellar clouds to new stars, protoplanetary disks and possibly inherited by planetary bodies and comets (Ceccarelli et al. 2017; Öberg et al. 2021). In that endeavor, the analysis of primitive meteoritic and cometary materials, as well as of samples from return-

missions, is pivotal. Dedicated analytical platforms (spectroscopy, microscopy, nanoscale secondary ion mass spectrometry, mass spectrometry, chromatography...) are crucial to characterize the soluble and insoluble organic matter and the mineral phase, to investigate the chirality of the molecular components, or to study isotopic fractionation, shedding some light on the interstellar chemical cycle and on the formation of the Solar System (Nittler and Ciesla 2016). These studies are also supported by comparison with laboratory analogues of dust grains and ices. The analysis of planetary samples benefits also from laboratory simulation reaction chambers, in particular for planetary or satellite atmospheres.

With the discovery of thousands of exoplanets, the question of the emergence of life and of the conditions of its apparition has come back to the frontline. Progress in this quest requires spectroscopic characterization of the atmosphere of the exoplanets (gas composition, vertical structure, presence of clouds/haze) as well as their host stars (stellar opacities) and relies heavily on laboratory data, theoretical calculations, and atmospheric photochemical modeling (Madhusudhan 2019). The determination of the internal structure of the exoplanet is also important to shed light onto the interaction between the atmosphere and the surface.

Concomitantly, a better understanding of the primitive Earth is essential to establish the physicochemical conditions for the emergence of life – element availability, water temperature, pH, ionic strength, energy, irradiation, gradients, and molecular diffusion – and identify the more adapted natural settings ranging from submarine hydrothermal vents to volcanic pools (Westall et al. 2018). Experiments also explore the role of exogenous matter in the emergence of life and allow us to better define the range of conditions in which this process could take place. The advent of biochemical systems likely does not solely result from more complex or diverse chemistry but from a specific organization that is self-sustaining and able to replicate itself; this remains to be demonstrated in the laboratory.

Laboratory astrophysics is a vibrant field of research shaped to open perspectives in related disciplines.

Laboratory Characterization of Meteorites

Hassan Sabbah

Institut de Recherche en Astrophysique et Planétologie (IRAP), Université de Toulouse (UPS), CNRS, CNES, Toulouse Cedex 4, France

Definition

Laboratory characterization of meteorites refers to the in-depth investigation of their physical and chemical features using analytical techniques. Based on their petrological characteristics, bulk chemical composition, and oxygen-isotope composition, meteorites are classified into recognized groups. Investigations of primitive meteorite and their components (chondrules, refractory inclusions, and matrix) have increased our understanding of the early solar system and its evolution. Characterization of presolar grains found in meteorites helped scientists in constraining models of nucleosynthesis in red giant stars and supernova. Investigating organic compounds in meteorites aims to understand the role of meteorites in delivering to Earth the components necessary for life.

Laboratory Dust Analogs

Karine Demyk

Institut de Recherche en Astrophysique et Planétologie, Université de Toulouse, CNRS, CNES, 9 Av. du Colonel Roche, 31028 Toulouse Cedex 4, France

Definition

Laboratory dust analogs are materials aiming at imitating cosmic materials to interpret astronomical observations. They may be natural samples but are in most cases synthesized by various techniques aiming at reproducing the main physical and chemical properties of cosmic matter inferred from observations: composition, structure, and size. Cosmic materials collected from Space or on Earth being very rare, analogs of silicate, oxide, carbon-based dust and ices are used in experiments simulating the evolution of cosmic dust in astronomical environments (e.g., photons and cosmic rays irradiations, shocks, gas-grain interaction).

Lactic Acid

Henderson James Cleaves II

Earth-Life Science Institute (ELSI), Tokyo Institute of Technology, Meguro-ku, Tokyo, Japan

Blue Marble Space Institute of Science, Washington, DC, USA

Center for Chemical Evolution, Georgia Institute of Technology, Atlanta, GA, USA

Definition

Lactic acid is an organic chemical compound that plays a role in several biochemical processes. It was first isolated in 1780 by the Swedish chemist Scheele. It is a carboxylic acid with the chemical

formula $\text{CH}_3\text{CH}(\text{OH COOH})$. It has a hydroxyl group adjacent to the carboxyl group, making it an α -hydroxy acid. Lactic acid is chiral and has two optical isomers. One is known as L-(+) or (S)-lactic acid, and the other, its mirror image, is D-(-) or (R)- lactic acid. L-(+)-Lactic acid is the biologically important isomer. In biochemistry, L-lactate is produced via reduction of pyruvate in a process of fermentation or anaerobic respiration. Lactic acid can also be derived from the deamination of alanine.

Lagrangian Points

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon, Meudon, France

Synonyms

[Lagrange points](#)

Definition

The Lagrangian points are five points in the orbital plane of two gravitationally bound bodies, where a small mass stays in equilibrium with respect to the other two, that is, remains at constant distances relative to them, despite the orbital movement. They are named after the Italian-French mathematician Joseph-Louis Lagrange who discovered

Lagrangian Points, Fig. 1 This cartoon locates the five Lagrange points in a two-massive body system

those five specific points while he reformulated the Newtonian mechanics. Three of the points, called L1, L2, and L3, are located on the line joining the two massive bodies, one is inside the segment joining the two bodies and the other two are outside. The two last Lagrangian points, L4 and L5, lie symmetrically on each side of this segment, each at the top of an equilateral triangle built on the two main bodies (see Fig. 1); these two locations are stable, that is, if the small mass at L4 or L5 is slightly displaced, it will be pulled back. In astronautics, Lagrange points L1 and L2 of the Sun-Earth system are of peculiar importance because they are locations where a spacecraft can be sent and maintained, far from the disturbing environment of Earth, but staying close enough for communication. Several space observatories have already been put at L2. Celestial objects are also found at Lagrange points, that is, the case of the Trojan asteroids at L4 and L5 of the Sun-Jupiter system.

Lamarck's Conception of Origins of Life

Stéphane Tirard

Faculté des Sciences et des Techniques de Nantes,
Centre François Viète d'Histoire des Sciences et
des Techniques EA 1161, Nantes, France

History

The French naturalist Jean-Baptiste de Monet, Chevalier de Lamarck (1744–1829) suggested an evolutionary theory in 1802, which was later called transformism. In this theory, he claimed that species changed and produced series. Transformations appeared when the environment and the habits acted on organisms for a long time.

In his theory, Lamarck gave a very important place to spontaneous generations. Indeed, for him, they were at the beginning of the series, and furthermore, describing them, I gave a short model of his theory.

Lamarck claimed that gelatinous matter could receive the “vital orgasm,” a sort of agitation of molecules opposed to universal attraction. “Uncontainable” fluids, caloric and electricity, could provoke this “vital orgasm.” Later, the containable fluids, gases and liquids, especially water, crossed this matter and deposited particles. This process was the beginning of nutrition. Lamarck considered that this steep of transformation corresponded to the structure of the simplest “polyp,” a monad just capable of elasticity. The continuous flow of water, always passing the same way, produced a little tunnel, the first digestive tube.

Two points have to be underlined. Firstly, in his description of the spontaneous generation process, Lamarck summarized how all the principal causes of transformism act on matter and produce changes in species. Secondly, Lamarck's theory on spontaneous generations currently exists in nature, and therefore vegetal and animal series are continuously beginning.

However, if Lamarck spoke of permanent spontaneous generation, he did not really deal with the primordial origin of life, which was difficult to conceive in the context of his theory and

especially regarding his own chemical conceptions, according to which all the matter on Earth was combined by living beings.

Landslide (Mars)

Alessandro Airo
Institut für Geologische Wissenschaften Tektonik
und Sedimentäre Geologie, Freie Universität
Berlin, Fachbereich Geowissenschaften, Berlin,
Germany

Definition

The main occurrence of landslide deposits on Mars are found within the Valles Marineris canyon system, where about 50 prominent landslides have been identified that originated from the canyon walls leaving behind curved scars cut into the canyon rim. The ages of landslide deposits in the Valles Marineris canyon system range from 3.5 Ga to as little as 50 Ma, implying that the triggering mechanism is ongoing and that the process of mass wasting is based on a non-changing flow rheology (Quantin et al. [2004a](#)).

If the mass wasting processes at Valles Marineris were supported by gas, fluids, or a basal lubrication remains debated. The geometric relation between run-out distance and landslide volume suggest predominantly dry mass wasting conditions (Soukhovitskaya and Manga [2006](#)), while the geometric relation between run-out distance and vertical drop imply a high mobility of the landslides and therefore indicate a fluidization process facilitated by the presence of a gas or a liquid (Quantin et al. [2004b](#)). The later mechanism is supported by dynamic model simulations showing that the landslide geometry matches best if a small fraction of liquid or gas is present (Harrison and Grimm [2003](#)). Others have argued that the great mobility of the landslides has been due to basal lubrication by subsurface ice or evaporites (De Blasio [2011a](#)).

The aureole deposits at the lower flanks of Olympus Mons may also represent landslide

deposits, however slower processes such as gravity spreading may have caused their formation. With a run-out distance of up to 700 km and a volume of almost one million cubic kilometers these are likely the largest landslide remnants in the solar system. Numerical studies suggest their extremely long run-out distance only to be possible through lubrication by water or ice, which might indicate the former presence of a northern ocean (De Blasio 2011b).

Massachusetts, Amherst, MA, USA

Definition

This is a theoretical model of bimolecular chemical reactions on solid surfaces in which two atoms or molecules are adsorbed on the surface and at least one diffuses on the surface until both are close enough to interact. In the interstellar medium, the formation of molecular hydrogen is thought to occur primarily through reactions on the surfaces of dust grains (See Wakelam et al. 2017).

Laplace Resonance

Rory Barnes
Astronomy Department, University of
Washington, Seattle, WA, USA

Definition

The Laplace resonance among orbiting bodies is a series of two consecutive 2:1 ► [mean motion resonances](#), making a 4:2:1 period ratio among the three bodies. Among Jupiter’s Galilean satellites, Io, Europa, and Ganymede are in the Laplace resonance. This commensurability was first pointed out by Pierre-Simon Laplace and now bears his name. This interaction prevents the orbits of the satellites from becoming perfectly circular due to tidal interactions with Jupiter and therefore permits tidal heating of Io and Europa. Three of the extrasolar planets orbiting the star Gliese 876 are also in a Laplace resonance.

Definition

The Large Millimeter Telescope/Gran Telescopio Milimétrico “Alfonso Serrano” (LMT) is a 50 m diameter single-dish radio telescope optimized for astronomical observations at millimeter wavelengths ($0.85 \text{ mm} < \lambda < 4 \text{ mm}$). The project is a binational collaboration between Mexico and the USA, led in Mexico by the Instituto Nacional de Astrofísica, Óptica y Electrónica and in the USA by the University of Massachusetts, Amherst. The LMT is an open-air telescope at an altitude of 4600 m on a mountain in the Mexican state of Puebla (latitude about +19°). The LMT began scientific observations with the inner 32 m of the dish in 2013; the full 50-m diameter surface was completed in 2018, making the LMT the most sensitive single-dish radio telescope in the world operating at millimeter wavelengths. It has already shown that it is an important link in millimeter-wavelength ► [VLBI](#) experiments.

Larson's Law

Steven W. Stahler
Department of Astronomy, University of
California, Berkeley, CA, USA

Definition

Larson's law is an empirical relationship, discovered by Richard Larson in 1981, between the size of a ► [molecular cloud](#) and its internal velocity dispersion. Larson found that the average velocity dispersion within a cloud is proportional to its size raised to a power n . This relation holds for clouds ranging in size from about 0.1 to 100 parsecs. Subsequent studies have confirmed the law, with n currently measured as 0.5. The theoretical basis of Larson's law is still not understood. The existence of this relationship may signify that the diffuse gas spawning molecular clouds is dominated by turbulent motion. Dense cores, the clouds that form individual stars, have sizes in the order 0.1 parsec and have internal velocities that do not obey the law.

Definition

The last universal common ancestor (LUCA) or cenancestor is the most recent ancestor from which all currently living species have evolved.

Overview

The idea that all life is related by common ancestry can be traced back to the publication of *The Origin of Species* by Charles Darwin (1872), where he wrote in the last chapter of his book, "...I should infer from analogy that probably all the organic beings which have ever lived on this earth have descended from some one primordial form, into which life was first breathed." However, it was not until the second half of the twentieth century, with the analysis of molecular sequences, that the modern discussion of the nature of the last universal common ancestor (LUCA or cenancestor) began.

Initially, Woese and Fox (1977a) suggested that the ancestor of ► [Bacteria](#) and ► [Eukarya](#) (the main lines of descent known at that time) was a *progenote*, i.e., a primitive entity with an imprecise relationship between ► [genotype](#) and

► [phenotype](#). Later on, the use of a small subunit of the rRNA molecule as a phylogenetic marker led to the discovery of ► [Archaea](#) as a third line of descent. Accordingly, the definition of the progenote was extended to include the three cellular domains (Bacteria, Archaea, and Eukarya), and by 1977, Woese and Fox suggested that the three domains evolved independently from the progenote.

This picture of the last universal ancestor began to change when Gogarten et al. (1989) and Iwabe et al. (1989) used ► [paralogous genes](#) to find the root of the universal tree of life. Both analyses showed that the root of the universal tree was placed in the branch leading to Bacteria, suggesting a bacterial-like universal ancestor. This picture was reinforced by a compilation of shared traits among the three cellular domains that indicated that the last ► [common ancestor](#) was already a complex organism more similar to present-day bacteria than to progenotes (Lazcano et al. 1992).

Then, the first comparative genome analysis led to a controversy that continues to be unsolved today. In an attempt to identify the minimum gene set required for cellular life, Mushegian and Koonin (1996) compared the ► [genomes](#) of *Haemophilus influenzae* and *Mycoplasma genitalium*. The inferred minimum gene set contained 256 genes, most of them showing eukaryotic and archaeal homologues. Among the exceptions were seven key proteins involved in DNA replication, including the replicative DNA polymerase. Bacteria uses one kind of DNA polymerase while Archaea and Eukarya use another. This observation led to the proposal that the last universal common ancestor had an RNA genome (Mushegian and Koonin 1996) and that DNA evolved independently, twice (Leipe et al. 1999). Clearly, this proposal differs from previous suggestions of a more bacterial-like LUCA (Lazcano et al. 1992). The proposal that the cenancestor had an RNA genome was contested by Becerra et al. (1997), arguing that caution should be taken in backtracking characteristics of the cenancestor when only complete ► [genomes](#) from parasitic organisms are taken into account, because those genomes are prone to secondary gene loss.

However, the lack of homology between the Bacterial and Archaeal/Eukaryal replicative DNA polymerases continues to fuel the debate.

A new twist on the reconstruction of the coding capacities of LUCA came from the analysis of complete genome sequences. A pattern emerged as more genomes became fully sequenced from different lineages of the tree of life. A large number of phylogenies derived from universally conserved genes didn't reflect the canonical division of Archaea, Bacteria, and Eukarya. This led to the suggestion that in the long run, the process of ► [lateral gene transfer](#) dominates the history of life (Doolittle 1999). If this is indeed the case, then it would be impossible to reconstruct the gene complement of LUCA (Zhaxybayeva and Gogarten 2004). These observations led to the proposals of a universal common ancestor dominated by rampant horizontal or lateral gene transfer (Woese 1998). However, ► [phylogenetic trees](#) derived from gene content reinforced the separation between Archaea, Bacteria, and Eukarya, suggesting that the history of life has not been completely dominated by lateral gene transfer (Tekaia et al. 1999). The level of lateral gene transfer throughout the history of life continues to be a matter of debate today (Williams et al. 2011; Kutschera 2011; O'Malley and Koonin 2011).

The similarities between extant cells suggest that LUCA did not emerge from the primordial soup (Arrhenius et al. 1999). For instance, genes involved in transcription and translation (the so-called informational genes) are highly conserved among Archaea, Bacteria, and Eukarya and must have been present in LUCA. There is also powerful statistical evidence of the monophyly of universally conserved genes (Theobald 2010). However, the nature and the level of complexity of the last universal common ancestor have remained controversial. Proposals range from a progenote level of organization where horizontal gene transfer plays a prominent role (Woese 1998) to highly complex cells similar in nature to extant prokaryotes (Becerra et al. 2007). Other topics of discussion include the nature of its genetic material (Leipe et al. 1999), the nature of its cellular organization (Penny and Poole 1999;

Glansdorff et al. 2008), and the role played by viruses in the evolution of LUCA (Forterre 2006).

Basic Methodology

In principle, the nature of LUCA can be inferred by identifying those genes universally conserved among Bacteria, Archaea, and Eukarya (Fig. 1). Drawbacks to this methodology include secondary gene loss (which leads us to underestimate LUCA's gene content) and lateral gene transfer (which, on the contrary, leads us to overestimate LUCA's gene content). See Fig. 2.

Key Research Findings

This is a (nonexhaustive) chronological list of key research findings in this field:

- The concept of the progenote as universal ancestor is suggested (Woese and Fox 1977a).
- The division of life into three domains (Archaea, Bacteria, and Eukarya) is discovered by using a small subunit of rRNA as a phylogenetic marker (Woese and Fox 1977b).
- By using paralogous genes, the root of the tree of life is positioned in the bacterial branch (Gogarten et al. 1989; Iwabe et al. 1989).
- Comparison of homologous genes from the three domains of life indicates a last common ancestor similar in complexity to extant prokaryotes (Lazcano et al. 1992).
- By comparing the first two completely sequenced genomes with gene sequences available in databases, a LUCA with an RNA-based genome is proposed (Mushegian and Koonin 1996).
- An important argument is provided to support the theory that proteins predate DNA (Freeland et al. 1999).
- The first inference of the gene complement of the last common ancestor by using genomes from the three domains of life is made. An ancestor similar in complexity to extant prokaryotes is suggested (Kyrpides et al. 1999).
- The inferred G + C content of LUCA appears to be incompatible with hyperthermophily (Galtier et al. 1999).
- The genetic core of the last common ancestor (as inferred from universally conserved genes showing three domain phylogenies) is comprised of mostly ribosomal proteins and a few proteins involved in DNA polymerization, (Harris et al. 2003).
- Most estimates of the gene complement of the last common ancestor are comprised of between 500 and 1,000 protein-coding genes (Mushegian 2008).

Last Universal Common Ancestor, Fig. 1 (a) Phylogenetic position of LUCA (in this case the root of the universal tree of life is shown in the Bacterial clade);

(b) The gene complement of LUCA can be inferred from conserved homologous traits among Archaea, Bacteria and Eukarya

Last Universal Common Ancestor, Fig. 2 Our accuracy to reconstruct the gene complement of LUCA is inversely related to the number of secondary gene losses and lateral gene transfer events along the history of life on earth

- Statistical evidence of the monophyly of universally conserved genes is provided (Theobald 2010).

Applications

Understanding the nature of LUCA: its level of complexity, the chemical nature of its genome, its gene complement, and its level of similarity to modern cell lineages, among other aspects of its biology, are central questions in evolutionary biology.

Future Directions

There has been much debate on the level of complexity (number of genes) and the chemical nature (DNA or RNA) of the genome of LUCA, and the debate is far from over (Vanechoutte and Fani 2009; Morange 2011). Understanding the role played by lateral gene transfer along prokaryotic evolution, and whether it affects all kinds of genes or not, is central to backtracking characteristics of the cenancestor. More research in this direction is clearly needed. The chemical nature of membranes in LUCA is another aspect of its biology that deserves more attention (Peretó et al. 2004).

Finally, LUCApedia, which is a detailed database comprising genes likely to be inherited from the cenancestor, will, in all probability, be of great importance in the reconstruction of the genetic complement of LUCA, since LUCApedia has the potential to accelerate research into the nature of our universal ancestor (Goldman et al. 2013).

²Analytical-Environmental and Geo-Chemistry, Vrije Universiteit Brussel, Brussels, Belgium

Keywords

Asteroids · Comets · Gas planets · Impact craters · Impact process · Meteorites · Moon · Small bodies · Solar system dynamics

Synonyms

LHB; Lunar cataclysm

Definition

The term *late heavy bombardment* (or LHB) corresponds to an elevated frequency of collisions that affected the inner solar system between 4.0 and 3.8 billion years ago. The Earth preserved no trace of these major impacts. Traces of the LHB can be found on the highly cratered surfaces of the Moon and other planets such as Mars or in the age of the impact melt measured on meteorites originating from the asteroid belt. The LHB represents

either the slowly decreasing tail end of planetary accretion or a cataclysmic event localized in time, perhaps triggered by a readjustment of the orbits of the giant planets long after the formation of the solar system.

Overview

The current stratigraphic timescale places the late heavy bombardment (LHB) period in the beginning of the Archean (in the Eoarchean Era), coeval, or slightly before the occurrence of the oldest metamorphosed terrestrial sediments outcropping in Isua (Greenland). The lunar crust started to crystallize around 4.44 Ga ago, and the morphology of the highlands displays a dense concentration of impact craters excavated prior to the emplacement of the first volcanic flows of the mare plains after 3.8 Ga. The LHB is now clearly established all over the inner solar system; it is recorded on the Moon, Mars, and in meteorites (Marchi et al. 2013), whose parent bodies originated in the asteroid belt.

However, the magnitude and frequency of the collisions taking place between the end of planetary accretion around 4.5 Ga ago and the start of the Archean at 4.0 Ga has been a matter of controversy for a long time. Two end-member views compete (Fig. 1), although other intermediate scenarios have also been proposed. The first hypothesis assumes that the frequency of impacts declined slowly and steadily after the end of planet accretion, in such a way that the bombardment frequency remained high (relevant to current) until 3.9 Ga ago (e.g., Hartmann et al. 2000). According to this view, the so-called LHB is not an exceptional event. Rather, it forms the tail end of a ~500 million year period, during which the Earth and the inner solar system were subject to devastating collisions, with possible major consequences such as melting of the crust, ejection of the atmosphere, and vaporization of the oceans.

The second hypothesis advocates a post-accretion rapid decline in the frequency of impacts, down to a value possibly only slightly higher than today. This low impact rate might have persisted throughout the entire Hadean. The

LHB period around 3.9 Ga thus represents an exceptional and cataclysmic event, characterized by a huge increase in the rate of collisions.

Basic Methodology

To establish a bombardment timeline on any planetary body, scientists have two possibilities. The first is to date impact events that affected whole rocks or their components and to compile statistics on the number of impact events as a function of age. An impact event is dated using isotopic chronometers that are sensitive to shocks. The other possibility is to count the number of craters on different surface units of known ages. The unit ages are established through isotopic analyses that reveal the crystallization age of its rocks.

Unfortunately, neither of these methods provide an unambiguous answer on the timeline of the ancient lunar bombardment.

The isotopic dating of impact melt rocks returned by the Apollo and Luna missions failed to identify impact events older than 3.92 Ga, suggesting the idea of a spike in the number of impact events at that epoch, i.e., the cataclysmic view (Tera et al. 1974). However, the argument can be made that most Apollo samples are related to the formation of the Imbrium basin, the largest “young” basin on the Moon and the only one precisely dated at 3.85 Ga. The melt phases in lunar meteorites confirm the deficit of impact ages older than 4 Ga (Cohen et al. 2000). This is important because meteorites likely originated from random locations on the Moon compared to the samples collected at a few landing sites. However, the impact age histogram provided by meteorites is much smoother than that derived from lunar samples, with some impact ages older than 4 Gy. Thus, it could be explained if there is a strong bias against recovering samples associated to the oldest events. Recent analyses of meteorite components (e.g., clasts in breccias) also reveal evidence for old impact events up to 4.2 Gy ago (Norman et al. 2006, 2016) and lunar zircons witness heating events, possibly associated to shocks, up to 4.3 Gy ago (Hopkins and Mojzsis 2015). These sporadic measurements of old

impacts, however, cannot be used to quantify how intense was the bombardment before 4 Gy and therefore to assess which of the two scenarios illustrated in Fig. 1 is correct.

The analysis of lunar crater densities also fails to yield an unambiguous view of the temporal evolution of lunar bombardment. There are ~12 basins which formed, according to stratigraphic analyses, between Nectaris basin and Orientale (the youngest basin on the Moon). Unfortunately, the age of Nectaris is not well known. If it is assumed to be 4.1 Ga, these 12 basins had ~300 Ma to form, and the decline of the bombardment rate (as measured from the densities of craters on Nectaris and Imbrium, respectively)

Late Heavy Bombardment, Fig. 1 Schematic representation of the flux of projectile on Earth between 4.5 and 3.5 Ga, (Modified after Kring 2003) both potentially explaining the intense bombardment around 4.0–3.8 Ga known as the LHB. The green curve shows a slow decrease of the bombardment, while the blue curve illustrates the hypothesis of a rapid decrease of the flux followed by a peak at the LHB time. In this case, the LHB would be due to some cataclysmic event shaking the structure of the solar system. It cannot be excluded that other cataclysmic events took place during the Hadean, but then their traces have been fully erased by the complete resetting of the Earth surface caused by the last event

occurred slowly. In this situation, it can be envisioned to extrapolate the bombardment rate backward in time till the Moon formation age, ~4.5 Ga ago. This has been done by Neukum and Ivanov (1994), whose proposed bombardment timeline has become the reference for the no-cataclysm hypothesis. Instead, if one assumes that Nectaris occurred at ~3.9 Ga, the 12 basins had less than ~100 My to form, and the bombardment rate declined so quickly between the Nectaris formation time and the Imbrium formation time that its extrapolation back to 4.5 Ga would lead to unrealistic predictions. For instance, the Moon would have accreted more than a Moon mass after its formation (!). In this case, the LHB can only be a cataclysmic event. Unfortunately, dating Nectaris radiometrically will not be possible until a new dedicated lunar mission is done.

In absence of an unambiguous empirical discrimination of the two bombardment scenarios, dynamical models can be useful to assess which scenario is more likely.

To explain a cataclysmic spike in the bombardment rate, a massive reservoir of planetesimals must remain intact during the planet formation epoch and the subsequent ~500 Ma and then, all of a sudden, be destabilized. This seems to be in conflict with the classical view according to which the solar system did not undergo substantial modifications after its formation. Gomes et al. (2005; the “Nice model”) designed a scenario that explains the origin of a cataclysmic LHB. In the Nice model, the giant planets formed on (or migrated to) quasi-circular, coplanar orbits, between approximately 5.5 and 12 AU. This orbital configuration was much more “compact” than the current one, where the planetary orbits are located from 5.2 to 30 AU. A massive disk of planetesimals surrounded the planetary system, extending outward from a few AUs beyond Neptune. Perturbations between planets and planetesimals eventually drove the planets into an unstable configuration. This led to a short phase of close encounters among the giant planets. As a result of these encounters, the orbits of Uranus and Neptune became eccentric, and the farthest planet penetrated into the disk. This event dispersed the

disk completely. The interaction between planets and planetesimals eventually parked the planets onto their current orbits. About 10^{-3} of the original planetesimals probably remained trapped in the Kuiper belt. The change in the dynamic structure of the giant planet system also depleted severely the main belt asteroid population, particularly its innermost region (Bottke et al. 2012). Escaping asteroids dominated the impact flux onto the terrestrial planets, causing an impact spike.

If there is ample evidence that a Nice model-like dynamical instability of the giant planets really occurred in the solar system (see for instance Nesvorný 2018, for a review), it is not sure that such an instability occurred after 500 My, i.e., at the LHB time. The timing of the instability depends critically on the distance between the original orbit of Neptune and the inner edge of the trans-Neptunian planetesimal disk. What this distance was is not known a-priori, leaving again an ambiguity on which of the scenarios illustrated in Fig. 1 is correct.

Key Research Findings

An important argument against Neukum and Ivanov's extrapolation of the bombardment timeline was that, assuming that the projectiles had an asteroid-like size distribution, it would imply the Moon accreted after its formation a mass of 1.3×10^{20} kg, which is five times larger than that inferred from the abundance of highly siderophile elements (HSE) in the Moon's mantle and crust (Morbidelli et al. 2012). However, Morbidelli et al. (2018) showed that the HSEs accreted prior to the final crystallization of the lunar mantle might have been sequestered in iron sulfides accumulated in the mantle's subsurface layer; the subsequent lunar mantle overturn would have brought this material to the core-mantle boundary from where iron sulfide and HSEs passed into the core. Thus, only the material accreted after the mantle overturn would reflect in the current HSE mantle budget. Consequently, if the lunar mantle completed its crystallization and overturned 4.35 Gy ago – as argued in some thermal evolution models (Elkins-Tanton et al.

2011) and deduced from various lines of evidence (Borg et al. 2015) – the current HSE budget of the Moon would be consistent with the declining bombardment envisioned by Neukum and Ivanov (Zhu et al. 2019).

Similarly, the Neukum and Ivanov bombardment timeline predicts the formation of more than 150 basins on the Moon. The recent GRAIL mission, that detected impact structures by measuring gravitational anomalies, inferred the existence of only 38–50 basins all over the Moon surface (Neumann et al. 2013), but recent work (Miljković et al. 2021) showed that all basins formed prior to the complete crystallization of the lunar mantle would leave no signature in the gravitational field of the Moon.

An important constraint on the timing of the dynamical instability of the giant planets, possibly associated to the lunar bombardment spike, has been recently obtained by combining dynamical and collisional evolution models. The idea is that the later was the instability, the longer the trans-Neptunian disk remained massive and collisionally evolved. In particular, collisions can dissociate the components of binary planetesimals; thus, assuming that all planetesimals formed as binaries, the current binary fraction observed in the Kuiper belt and among Jupiter's Trojans – which are populations trapped from the original trans-Neptunian disk – gives an upper bound on the number of collisions that the original trans-Neptunian population suffered. Using this approach, Nesvorný et al. (2018) found that the dispersal of the trans-Neptunian disk, and hence the giant planet dynamical instability, should have occurred no later than 100 My. This is much earlier than the LHB time. This result has put serious doubts on the cataclysm scenario for the origin of the LHB.

For a long time, a dynamical argument against the scenario of the tail-end bombardment was that any unstable population of small bodies in the inner solar system would have decayed faster than assumed by Neukum and Ivanov (1994), particularly when collisional grinding is also taken into account (Bottke et al. 2007). A faster decay would imply an unrealistically large initial projectile population, perhaps with a total mass up to an Earth

Late Heavy Bombardment, Fig. 2 Number of craters larger than 1 km in diameter that should have formed on the Moon per unit surface, as a function of terrain age, in the case the giant planet instability occurred at about the Moon formation time (about 4.5 Gy ago). The black, cyan, and green curves show respectively the density of craters produced by asteroids, planetesimals leftover from the terrestrial planet formation process, and trans-Neptunian comets. The red curve shows the sum of these three contributions. The colored dots show the measured densities of craters on units of known radiometric ages. The horizontal line labelled “HSE constraint” shows the crater density corresponding to the delivery of a mass equal to that inferred from the HSE budget in the lunar mantle and crust, assuming an asteroid-like size distribution. The crossing of this line by the red curve at the age of 4.35 Gy shows that, in this scenario, HSEs must have been retained in the lunar mantle only since this date. (Adapted from Morbidelli et al. (2018))

mass. However, studies of terrestrial planet formation (Morbidelli et al. 2018) revealed that the planetesimals leftover from the planet accretion process do decay dynamically on a timescale comparable to that envisioned by Neukum and Ivanov (1994). Moreover, collisional grinding is important only for planetesimal populations initially carrying more mass than 0.1 Earth masses. For this amount of initial mass, and a size distribution similar to that of main belt asteroids, the dynamical decay of the

population allows to reproduce quantitatively well the density of craters at the surface of the Moon as a function of lunar-surface age (Morbidelli et al. 2018; Fig. 2).

Future Directions

Although modern models tend to prefer the tail-end bombardment scenario over the cataclysmic scenario, a definitive conclusion on the real timeline of the lunar bombardment can only be achieved with more data. The new surge of lunar space mission can bring decisive measurements in the next decade. Many of them will land in the South-Pole Aitken (SPA) impact basin, the largest and oldest unambiguous impact structure on the Moon. Dating SPA could be decisive. The tail-end-bombardment scenario predicts that it formed 4.35 Ga ago. A significant older or younger impact age would instead strengthen the cataclysmic scenario. Similarly, dating old surface units, for instance the highlands on the far side of the Moon, or dating the Nectaris basin precisely, could allow extending beyond 4 Ga the database of the density of craters as a function of age, solving, once forever, this long-standing controversy on the nature and the origin of the late heavy bombardment of the Moon.

Late Veneer

Francis Albarède

Laboratoire de Géologie de Lyon, Ecole Normale Supérieure de Lyon, Lyon Cedex 7, France

Definition

The term *late veneer* refers to the late accretion of asteroidal or cometary material to terrestrial planets. Iron and nickel segregation during core

formation leaves the mantle of the planets depleted in siderophile elements, notably platinum-group elements. The modern abundances of these elements in the terrestrial mantle greatly exceed the level expected from such a wholesale removal of metal. It is therefore surmised that 0.5–1.5% of chondritic or cometary material was brought to the planet by the late veneer after core formation (Dauphas and Marty 2002; Maier et al. 2009). This hypothesis is germane to the issue of water delivery to the Earth.

History

Ringwood (1966) pointed out that the abundances of siderophile elements such as Ni, Co, Pt, and Os in the upper mantle are remarkably higher than the values indicated by low-pressure partitioning experiments of these elements between metal and silicate phases. Chou (1978) suggested that about one percent of material resembling ► [carbonaceous chondrites](#) was added to the Earth after core formation.

Overview

The excess of siderophile elements in the terrestrial mantle (the crust allotment may safely be neglected) with respect to the level of abundance expected from metal/silicate equilibration in the course of core segregation stirred strong debates (e.g., Drake and Righter 2002) and generated abundant experimental work. There is nothing really contentious about highly siderophile elements, such as platinum-group elements (Pt, Os, Ir, Pd, Ru, Rh), for which the metal/silicate distribution coefficient is in the range 10^4 – 10^6 (Holzheid et al. 2000). The very existence of the excess was, however, challenged for transition elements such as Ni and Co (Li and Agee 1996) with the assumption that core segregation took place under pressures in excess of 35 GPa, which corresponds to mid-mantle depth (Wade and Wood 2005). The best estimate of the proportion of late veneer in the Earth is therefore given

by the platinum-group elements excesses and is about 0.7%.

Dynamic models of planetary accretion can accommodate such a late delivery of chondritic material. At the end of the oligarchic stage of planetary accretion, a few tens of million years after the formation of the Sun, when only a few tens of Mars-sized bodies were left to plow into disks of asteroids, the main effect of Jupiter's attraction (resonances) was to knock asteroids off their orbits and sling them out of the Solar System or into the inner Solar System and the Sun itself (Morbidelli et al. 2000). Earth's capture cross section is thought to have been large enough that some of these projectiles hit our planet. Precisely how many of these landed on Earth is not well understood, but the tail of the asteroid shower seems to have lasted well beyond the formation of the terrestrial core.

The relevance of the late veneer to the delivery of water to the Earth is clear. Because most of its constitutive material accreted in the hot inner Solar System, our planet should be even more depleted in volatile elements, such as S, C, N, Cl, Zn, Pb, and, most significantly, water, than the presence of conspicuous ocean and atmosphere indicates. ► [Comets](#) were the preferred volatile carriers (Owen and Bar-Nun 1995) until it was realized that water from these objects was twice too rich in deuterium with respect to hydrogen compared to seawater. Attention then turned to chondritic asteroids from the outer Solar System, which carry water in excess of 10% (Morbidelli et al. 2000). Not everybody agrees that water came in late with the late veneer rather than early, but the record of a process that fractionated terrestrial volatile from refractory elements some 100 ± 50 million years after the formation of the Solar System is clearly found in both U-Pb and the I-Pu-Xe chronometers (Albarède 2009).

The late veneer should not be confused with the ► [Late Heavy Bombardment](#), which is dated at about 3.9 Ga on the Moon. The LHB is responsible for the largest lunar craters such as Imbrium. Abundant and large impacts of similar age are observed on Mars and inferred on some asteroids. The LHB is thought to be associated with the

disruption of a large asteroid or to the perturbation of the asteroid belt by the rapid migration of the giant planets (Gomes et al. 2005).

Late-Stage Accretion

Avi M. Mandell

NASA Goddard Space Flight Center, Greenbelt, MD, USA

Synonyms

[Late-stage chaotic growth](#)

Definition

Late-stage accretion refers to the final stage in the formation of ► [terrestrial planets](#). At the beginning of this stage, the solid mass in the ► [protoplanetary disk](#) is roughly equally divided between ► [planetary embryos](#) and smaller ► [planetesimals](#). Embryos grow large enough to gravitationally perturb each other onto crossing orbits, triggering a phase of giant embryo–embryo collisions. In most cases, the chaotic growth stage is thought to start 1–10 million years after the start of accretion and to last for another 10–100 million years, generating amounts of collisional debris. The impact that formed the Earth–Moon system is thought to have been the last giant impact on Earth. It occurred during the chaotic growth stage, 4.45 Gy ago.

Latent Heat

Raymond Pierrehumbert

Department of Physics, Clarendon Laboratory, University of Oxford, Oxford, UK

Keywords

Clouds · Latent heat · Phase change

Definition

When a substance changes from one form to another (e.g., gaseous carbon dioxide condensing into dry ice), energy is released or absorbed even if the temperature of the mass is unchanged after the transformation has taken place. This happens because the amount of energy stored in the form of intermolecular interactions is generally different from one form, or phase, to another. The amount of energy released when a unit of mass of a substance changes from one phase to another, holding temperature constant, is known as the latent heat associated with that phase change (J/kg in mks units).

Overview

Condensable substances play a central role in the atmospheres of many planets and satellites. On Earth, it is water that condenses, both into liquid water and ice. On Mars, CO₂ condenses into dry ice in clouds and in the form of frost at the surface. On Jupiter and Saturn, not only water but also ammonia (NH₃) as well as a number of other substances can condense. The thick clouds of Venus are composed of condensed sulfuric acid. On Titan, it is methane, and on Neptune's moon Triton, nitrogen itself condenses. Water has an unusually large latent heat; the condensation of 1 kg of water vapor into ice releases nearly five times as much energy as the condensation of 1 kg of carbon dioxide gas into dry ice. This is why the relatively small amount of water vapor in Earth's atmosphere can nonetheless have a great effect on atmospheric structure and dynamics. Ammonia also has an unusually large latent heat, similar to water's. In both cases, the anomalous latent heat arises from the considerable energy needed to break hydrogen bonds in the condensed phase. When air rises, it cools by adiabatic expansion, and if it gets cold enough that one of the components of the atmosphere begins to condense or the partial pressure of one of the compressed atmospheric components surpasses the saturation vapor pressure, latent heat is released. This makes the rising air parcel warmer than the dry adiabat (no energy input to the parcel) would predict. If we assume further that the

condensation is efficient enough that it keeps the system at saturation, the resulting temperature profile is commonly referred to as the moist adiabat, regardless of whether the condensing substance is water vapor (as on Earth) or, e.g., CO₂ on Mars or methane on Titan.

Lateral Gene Transfer

Purificación López-García
Unité d'Ecologie, Systématique et Evolution,
CNRS UMR8079 Université Paris-Sud 11, Paris,
France

Keywords

Conjugation · Transduction · Transfection · Transformation

Synonyms

[HGT](#); [Horizontal gene transfer](#)

Definition

Lateral or horizontal gene transfer is the acquisition of genetic material from another organism without being its offspring, although it frequently

refers to transfer from organisms belonging to another species. It contrasts with vertical gene transfer, which is the acquisition of genetic material from an ancestor.

Overview

There are three known mechanisms of lateral gene transfer: ► [transformation](#), ► [transduction](#), and ► [conjugation](#). Transformation implies the acquisition of naked DNA, for example, from lysed cells, by a recipient cell. Transduction implies the acquisition of ► [DNA](#) via ► [virus](#) intermediaries, which may infect one host, recombine with its ► [genome](#), and pick up some genes that can then be transferred to a second host. Conjugation involves the transfer of large DNA segments via specialized (conjugative) plasmids that are mobilized between cells through particular ► [pili](#). Thought to be a relatively minor process some years ago, lateral gene transfer is known today to play and have played a very important role in both prokaryotic and eukaryotic evolution. In the case of eukaryotic cells, the nuclear genome acquired massive amounts of foreign genes from the endosymbiotic ancestors of organelles (mitochondria, primary and secondary plastids). In the case of prokaryotes, gene transfer is very active and plays a readily adaptive role under particular selective pressures (e.g., the transfer of antibiotic resistance genes when faced with antibiotic pressure). Lateral gene transfer in prokaryotes appears so widespread that some authors even question the possibility of reconstructing a tree of life proceeding by bifurcation and think that organismal evolution would be better depicted by a “web of life” with anastomosing (reconnecting) branches. Other authors think, on the contrary, that although lateral gene transfer is important, it is not rampant. In that case, the reconstruction of a tree of life using a “core” of conserved genes would be possible.

Lava Tubes

Ernst Hauber
Deutsches Zentrum für Luft- und Raumfahrt
(DLR) e.V, Institut für Planetenforschung, Berlin,
Germany

Definition

Lava tubes are natural conduits through which lava travels beneath the surface of a lava flow (definition by U.S. Geological Survey). When the lava supply stops, the lava drains downslope and leaves a partially empty conduit (a lava cave). When the roof of a lava tube collapses, a so-called *skylight* (an opening in the roof) is formed. Skylights have been identified in high-resolution images from orbit on the Moon and Mars. Lava tubes are thought to exist on all terrestrial planets and the Moon, and perhaps even on the Jovian satellite, Io.

Synonyms

Anthony van Leewenhoek; Antonie van Leeuwenhoek; Antonius a Leeuwenhoek; Antontj Leeuwenhoeck

Definition

Antony van Leeuwenhoek (1632–1723) is one of the most influential men in the foundation of biology. Leeuwenhoek's unique method of grinding lenses into his own microscope design led to his discovery of ► [bacteria](#) and other ► [microorganisms](#). Born in Delft, Holland, Leeuwenhoek lacked formal science training and worked as a draper, while making remarkable microscopy discoveries by night. Leeuwenhoek was meticulous in recording his findings and corresponded with the Royal Society of London for decades. Through his work, Leeuwenhoek has ultimately been regarded as the “Father of Microbiology.”

Overview

Over the last few decades, numerous discussions have taken root regarding the vast diversity of microorganisms and their essential role in biogeochemical systems, the environment, and health. Earth has been inhabited by microbes, the ancestors of present-day bacteria and ► [archaea](#), for more than three billion years, and yet their existence was unknown before Leeuwenhoek's observations. The significance of his discoveries cannot be overstated: no one suspected the presence of microscopic life even though most of life is microbial. Leeuwenhoek was the first to see the enormous numbers and diversity of microbes, organisms that had no name. He called them “diergens,” diminutive of “dier,” the Dutch word for “animal,” in English, “little animals” or “animalcules.”

Soon after its founding in 1660, The Royal Society of London began asking men from surrounding countries to offer any knowledge they had in science. At this point, Leeuwenhoek had been grinding, polishing, and mounting lenses to

create microscopes in his spare time between selling buttons and ribbon. A surviving Leeuwenhoek microscope magnifies 266 times to a resolution of approximately 1 μm . In 1673, Dr. Reinier de Graaf, a Dutch Physician familiar with Leeuwenhoek, wrote to Henry Oldenburg, Secretary of The Royal Society, encouraging Oldenburg to reach out to him. Leeuwenhoek recorded his findings over the next 50 years in letters to The Royal Society, which published his letters.

Leeuwenhoek discovered protozoa in 1674 while looking at rainwater and in 1676 he discovered bacteria in pepper-infused water during an investigation of “the cause of the hotness or power whereby pepper affects the tongue. . .” Another noteworthy contribution was the discovery of intestinal protozoa and bacteria of humans through observations of excrement. In 1681 he wrote in a letter to the Royal Society, “I have also seen a sort of animalcules that has the figure of our river-eels: these were in very great plenty and so small withal. . .” He goes on to say, “These had a very nimble motion, and bent their bodies serpent-wise, and shot through the stuff as quick as a pike does though the water.” It is likely that Leeuwenhoek had discovered spirochetes, the first indication of the existence of bacteria as normal residents of the intestines of humans.

Leeuwenhoek continued documenting his findings in rapt succession, always challenging his predictions in hopes of making more connections. He documented and quantified rapid microbial growth and conducted experiments relevant to his observations, never attributing the appearance of vast numbers of microbes to spontaneous generation. He looked at spittle from his mouth as well as from his wife and daughter; people he considered to have “clean teeth” and illustrated the existence of unique microbes. Despite his age, Leeuwenhoek never stalled in his work. Although his letters to the Royal Society were not as timely as in the past, they never stopped. Leeuwenhoek set the foundation for microscopy, microbiology, and biology, as we know it. His work surrounding bacteria, protozoa, parasitic, and anaerobic organisms, the human body, and the diversity of life was revolutionary. It is a marvel to comprehend how

much Leeuwenhoek covered with such limited means at his disposal. Leeuwenhoek's work set the stage for advancing understanding of the origin and evolution of life on Earth.

Lemaître's Theory of Expanding Universe (History)

Stéphane Le Gars
Centre François Viète, Université de Nantes,
Nantes, France

Keywords

Astrophysics · Big Bang · Cosmogony ·
Cosmology

History

Today, Lemaître's name is closely connected to the idea of Big Bang. Indeed, Lemaître's works concerned the structure of the Universe and its origin, i.e., problems about cosmology and cosmogony.

After his studies at the Jesuit College of Charle-roi, in Belgium, he began studies at the Engineer School from the University of Louvain, but he gave

them up after World War I to dedicate himself to physics and mathematics. After his Ph.D., he received a grant from the Belgian government which let him take a course with Arthur Eddington for 1 year and made possible for him to complete his attainment in astronomy and general relativity fields. In 1924, he went to the USA, where he was a student at the Harvard College Observatory and at the MIT. He discovered at this time Hubble's recent works which showed that nebulae are distant galaxies, but not objects in our own galaxy. This discovery will be crucial for his further works.

For this purpose, in 1927, 2 years after being back in Belgium, Lemaître published an article titled "Un univers homogène de masse constante et de rayon croissant, rendant compte de la vitesse radiale des nébuleuses extragalactiques" ("A homogeneous universe with a constant mass and a growing radius, accounting for the radial speed of the extragalactic nebulae"). In this article, Lemaître explained his innovating ideas: Unlike the static universes taken off the general relativity by Albert Einstein and Willem De Sitter, Lemaître imagined a finished and expanding universe. Then, he drew every inference from this idea of expansion. As early as 1931, Lemaître suggested that the universe comes from a "primeval atom." Taking his knowledge of the general relativity, the new quantum theories and the first microphysics results into account, but also the recent observation data about the galaxy's speed removal, Lemaître was the first to establish significantly the idea of a beginning of the Universe. He even affirmed that cosmic rays are the relics of this first explosive stage of the cosmic history and emphasized the role of a nonzero cosmological constant.

Both priest and scientist, Lemaître has never had problem to conciliate at a personal level science and faith, avoiding always assimilating his cosmogonist ideas to any divine creation of the world.

Leucine

Kensei Kobayashi

Yokohama National University, Yokohama, Japan

Definition

Leucine is one of the 20 protein amino acids. Its three-letter symbol is Leu, and the one-letter symbol is L. Its chemical formula is $\text{HO}_2\text{CCH}(\text{NH}_2)\text{CH}_2\text{CH}(\text{CH}_3)_2$, which gives a molecular weight of 131.17, and its isoelectric point (pI) is 5.98. Among the 20 protein amino acids, leucine belongs to the group of amino acids whose side chains are simple hydrocarbons, together with glycine, alanine, valine, and ► [isoleucine](#). Leucine (side chain: $-\text{CH}_2\text{CH}(\text{CH}_3)_2$) and isoleucine (side chain: $-\text{CH}(\text{CH}_3)\text{CH}_2\text{CH}_3$) are isomers. Leucine has in addition 29 nonprotein ► [amino acid](#) isomers, such as norleucine (side chain: $-\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3$). Many of them have been identified in extracts from the Murchison meteorite.

LHS-1140b

Emeline Bolmont

Observatoire de Genève, Université de Genève,
Sauverny, Switzerland

Definition

LHS-1140b is a transiting planet which was discovered by the MEarth project in 2017 (Dittmann et al. 2017). It is a super-Earth 1.4 times the size of the Earth and with its orbital period of 24 days, it sits in the habitable zone of its small host star (only 15% the mass of our Sun). The planetary system is located 49 light years away, which makes this planet one of the closest habitable zone planet to our Earth.

In 2019, another planet was detected in the system, LHS-1140c, on a shorter orbit and therefore too hot to sustain surface liquid water (Ment et al. 2019).

Together with the TRAPPIST-1 planets, LHS-1140b is a good target for atmospheric characterization with the James Webb Space Telescope and the European-Extremely Large Telescope (e.g., Wunderlich et al. 2021).

Libration

Sean N. Raymond

Laboratoire d'Astrophysique de Bordeaux,
CNRS, Université de Bordeaux, Bordeaux,
France

Definition

Libration is the oscillation of an angle about a fixed value (as opposed to circulation, meaning the angle cycles through all possible values). In celestial mechanics, libration of certain angles such as the ► [apsidal angle](#) or certain resonant angles means that the system is in a state with a particular configuration. In other words, it is the libration of one or more resonant angles which indicates if a system of planets is in resonance.

Lichens

Leopoldo G. Sancho

Faculty of Pharmacy, Section of Botany,
Universidad Complutense, Madrid, Spain

Keywords

Symbiosis · Algae · Fungi · Poikilohydric ·
Extremophiles

Definition

Lichens are mutualistic symbiotic organisms composed of a fungus, usually an Ascomycete, which is intimately associated with a photosynthetic partner that is an alga or a cyanobacteria (also called blue-green algae), or sometimes both. The result is a stable, autotrophic form of life that uses carbohydrates produced by the photosynthetic partner to live and grow. Lichen symbioses involve around 20,000 species of fungi and around 100 species of green algae and cyanobacteria (Hawksworth and Lücking 2017). In addition to these fundamental components, other microorganisms such as bacteria, yeasts, and lichenicolous fungi have been identified in numerous lichen species (Grube and Wedin 2016; Spribille et al. 2016). The complexity of lichen symbiosis introduces some conceptual problems in the delimitation of lichen-forming species (Lücking et al. 2021).

Overview

In lichen symbioses, the fungal partner (mycobiont) makes up most of the structure of the lichen and absorbs water and nutrients from the surroundings as well as providing a suitable environment and protection for the metabolic activity of both partners. Many of the lichen-forming ascomycetes reproduce sexually producing ascomata mostly on the upper surface of the lichens. A high percentage of lichens can asexually reproduce the symbiosis via symbiotic propagules such as soredia and isidia. Lichens are extraordinarily diverse in size, color, and morphology and are divided into three main forms, crustose (deeply attached to surfaces), foliose (flattened leaf-like), and fruticose (bushy lichens usually attached by one point to the substrate) (British Lichen Society web page 2018). They show a wide ecological range, from the intertidal zones to the highest summits of the world and from the tropics to the poles, and can grow on soil, tree bark, leaves, mosses, and rocks as well as artificial substrates such as concrete and glass. In polar and alpine, tundra lichens are often the dominant vegetation (Green et al. 2007). They are also

an important component of the biological soil crust in arid areas (Maestre et al. 2012). Lichens are known for their slow growth that ranges from an increment in diameter of 0.01 mm year⁻¹ in some Antarctic crustose species to several centimeters per year by foliose and fruticose species (Green et al. 2011; Sancho et al. 2019). Lichenometry takes advantage of the slow growth and longevity of crustose lichens to estimate the exposure age of stone surfaces (Armstrong and Bradwell 2010). Lichens are also widely used as bioindicators of the air quality due to their sensitivity to oxidant pollution, mainly SO₂ (Cislaghi and Nimis 1997).

Lichens are poikilohydric organisms, that is, they desiccate and remain dormant, when their environment dries out, but can rehydrate when water becomes available again. Upon ► [desiccation](#), the lichens become dehydrated to a degree that halts most biochemical activity. In this dehydrated state, many lichens are highly tolerant to stress conditions and have even survived full exposure to space conditions (Sancho et al. 2007; de la Torre et al. 2020) and to simulated Mars atmosphere (de Vera et al. 2019). The reasons for this resistance are both molecular, special metabolites protect important molecules, and structural, where accumulation of lichen substances, especially in the upper cortex, account for the ability of these organisms to survive high radiation, including UV, and high vacuum. Many lichens can hydrate directly from water vapor or from snow crystals and, after rehydration, lichens from the most extreme habitats can resume their activity in minutes, even having been inactive for months or years. These features make lichens suitable material for experiments in astrobiology.

Definition

Although it is rather controversial whether the term “life” will ever fit into a definition, it could be conceived as “autonomy in evolution”: a complex network of self-reproducing *autonomous* agents whose individual (far-from-equilibrium, metabolic) organization is instructed by material records generated through an *open-ended*, historical process, in which that complex (collective-ecological) network evolves. In a minimal – and more operational – sense, this involves that any living system should be ultimately based on the dynamic intertwinement of a semi-permeable boundary (membrane), an energy transduction apparatus, and, at least, two complementary types of macromolecules: (enzyme-like) catalysts and (gene-like) templates.

Overview

In spite of its multifarious meanings and the intrinsic difficulty it has shown over the years to become a well-defined unanimous generalization, the concept “life” can still be regarded as a proper scientific target, with its own specific weight and implications, not only for biology (and closely

related disciplines) but for other fields of knowledge and research. Acknowledging that it is a notion that needs to be refined, made more precise and possibly further developed in the future, we consider that progress in the understanding of life is a scientifically relevant goal. This position is in contrast to the always present skeptical voices, e.g., those who think that life is simply a wrong category, because it does not help as a demarcation criterion; or that life cannot be linked to any “natural kind,” arguing on grounds of an “apparent” arbitrary or conventional character. In any case, the discussion below will just highlight several open problems linked to an interpretation of this concept in positive terms; several open problems that the investigation in Synthetic Biology, Artificial Life, Origins of Life, and, in particular, Astrobiology should contribute to solve in years to come.

The first problem is determining the universality of life. Although the planet Earth hosts a biosphere composed of an incredible variety of living forms, molecular biology has shown that they all share the same biochemical core, and the evolutionary theory proposes that they all derive from a common type of ancestral organism. Therefore, it becomes reasonable to wonder whether we are dealing with a single example of life, after all. Nobody has been able to synthesize alternative, completely different, living forms in the lab, so far, or to detect them elsewhere in the universe. And this poses a severe difficulty: how to discern the particular or contingent from the general and necessary attributes that characterize the living phenomenon. Comparative analyses across the huge diversity of organisms on Earth can be very helpful in that sense: they should give good indications of which are the indispensable set of mechanisms involved in the strikingly complex *organization* and *way to change over time* of living systems (in relation to non-living ones). Complexity sciences and, in general, bottom-up approaches coming from physics and chemistry should also add to that aim, showing that, whenever certain boundary conditions are met (during a suitable time span), matter tends to create organized structures; and only if these self-organized

structures bring about additional mechanisms for their long-term persistence can a minimal biological threshold of complexity and robustness be crossed.

A second problem, clearly connected with the first, regards finding out the adequate level of abstraction or specificity of the concept. In the last decades, the great advances in computational tools and simulation (*in silico*) techniques to analyze living systems, complementing traditional (in vitro and in vivo) experimental approaches, have raised the question of whether some biological features, or life itself, might be captured or even implemented at a symbolic, materially detached level. The strongest theses coming from the field of ► [Artificial Life](#) in the nineties pointed in that direction, proposing to conceive of life “as it could be” and not only as “we actually know it.” That debate is still open, but now shifting to a somewhat different arena: even if we acknowledge (as it is being generally acknowledged) that materiality plays an important role, what is the actual level of molecular specificity required for life? Are there chemical alternatives to ► [RNA](#), ► [DNA](#), ► [protein](#), etc. (that could play similar functional roles, as templates, catalysts, etc.)? Can a cell-free (or compartment-free) organism be built? Equivalently, can a genome-free organism be put together? If ever possible, for how long? What properties would these new kinds of “quasi-biological” systems have/lack? The now emerging discipline of Synthetic Biology (together with other novel enterprises, like Systems Chemistry) will hopefully address some of these questions soon. And Astrobiology, from its foundational steps, has also included them (or similar ones) in its research agenda: why water, why carbon, etc. (as key ingredients for life)? What minimal size (i.e., minimal internal molecular machinery) could an organism have? In so far as science provides means to answer these open issues, possibly through the fabrication of intermediate or semi-synthetic systems, or through the detection of extra-terrestrial systems with some life-like properties, it will be giving new clues to advance in our way of handling and maturing the general “life” question.

Finally, a third big difficulty of the concept “life” lies in its inescapable twofold dimension. All living phenomena relate, one way or the other, to the physically bounded organization of individual organisms, but are also embedded in the temporally and spatially much wider network of systems and relationships comprising the whole history of the biosphere. The former involves fundamental features that we, as organisms, naturally recognize in other living systems, like metabolism and adaptive agency, whereas the latter reflects larger-scale (but no less important) aspects, like the capacity to change and evolve through generations, or the more global interactive dynamics at the ecological level.

In reality, these two dimensions of life are deeply entangled. On the one hand, any known living being cannot exist but in the context of a collective network of similar systems. And this is clearly reflected in the fact that genetic components (which specify the metabolic machinery and organization of single biological entities), in order to be operational, must be shaped through a process that involves a great amount of individual systems and many consecutive generations, or reproductive steps. The unfolding of an evolutionary process by natural selection, based on heritable modular templates and genetic mechanisms, allows this peculiar form of organization we call “living matter” to explore many possible combinations and formulas to survive, providing extreme examples of adaptation that make any borderline within the living domain rather diffuse. Actually, evolution, beyond that intrinsic competitive/selective dynamics, weaves a collective network of increasingly complex and entangled cooperative relations among entities at different phenomenological levels and with different cohesive strength.

But, on the other hand, the organismic dimension of life, namely, its expression in the form of individual agents, is also crucial to understand it. However embedded in evolutionary and ecological webs living systems might appear, their metabolic functioning still points to a basic organizational core that should be properly characterized. If the essence of biological organization is conceived as a web of diverse interactions

among – rather than *within* – different bio-entities (extending the idea of living system to molecular replicators, viruses, organelles, parasites, symbionts, etc.), it will not be possible to determine whether organisms should be taken as a basic starting point (i.e., as a highly integrated and cohesive type of organization that gets progressively complex) or just as some occasional result of that ongoing dynamics of loose cooperative relations among a plurality of bio-entities. This is an important issue, because without such a highly integrated and cohesive individual organization, it would be very difficult to give a proper account of metabolism, development, agency, unit of selection, etc., or to make a clear-cut distinction between organisms and other forms of cooperative or “ecological” networks. Furthermore, life seems to demonstrate, in the course of evolution, that increasingly complex kinds of individual agents have emerged and developed, bringing forth progressively sophisticated interactive capacities (cognitive ones included).

Nevertheless, the apparent tension between these two aspects or conceptions of life can be channeled constructively. Indeed, what really matters is their deep entanglement, since a process of open-ended evolution cannot occur except in the context of a population of individuated metabolic systems (i.e., organisms); and, conversely, the unfolding of organisms and their long-term maintenance depend on their insertion in an open-ended evolutionary pathway. So it is really the integration of these two dimensions that provides a complete, rich enough picture of the phenomenon of life. Such a synthetic conception could be interpreted, in addition, as an attempt to bring together the main results and theoretical legacy of two different traditions in biology: the physiological-biochemical tradition, focused on immediate or “proximate” causes, and the evolutionary-historical tradition, interested in the final or “ultimate” ones.

Muséum National d’Histoire Naturelle, Brunoy, France

History

Since Copernicus demonstrated in 1543 that the Earth was not located at the center of the universe but was revolving around the Sun like the other planets, the Earth took the status of a simple planet among the others. Stars became suns and planets became earths that could be inhabited. The consequence of this view of the universe was that each planet of the solar system could be peopled with various inhabitants. In fact, this changing in the position of the Earth was not a rapid scientific revolution. The heliocentric theory of Copernicus produced a slow shift in the religious, philosophical, and scientific mentalities. The unfortunate pioneer of the extraterrestrial debate at the end of the sixteenth century, Giordano Bruno (1548–1600), who supported the Copernican system, had to come up against the religious dogma and to try to remove a very deep-rooted belief about our place in the universe.

A new epoch of observations was born in 1609 when Galileo Galilei (1564–1642) began to study in details the surface of the Moon thanks to his telescope recently devised. He also discovered four satellites orbiting ► [Jupiter](#) and the impact of this discovery was decisive to provide confirmation of the triteness of our planet among the celestial bodies of the solar system. The

seventeenth century saw the definitive affirmation of the Copernican theory thanks to Kepler's works demonstrating that planetary orbits were not circles but ellipses. Planetary motions were completely demystified and the position of the Earth as an ordinary planet going around the Sun could no more be challenged.

Galileo's observations and Kepler's works led to a new debate about the plurality of worlds. Literary and scientific works flourished about the habitability of our neighbor the Moon in a context however still controlled by religious authority.

Fascinated by the new paradigm of heliocentrism, Kepler (1571–1630) wrote a little book mixing didactic and fiction style, named *Somnium, Sive Astronomia Lunar* (*The Dream, or The Astronomy of the Moon*). This book, which could have been considered as provocative during Kepler's life, was published posthumously by his son in 1634 (whereas it was started in 1609). The interesting point was that Copernican astronomy was illustrated by a transposition in order to make clear the heliocentric viewpoint: how does the Earth look from the lunar surface for inhabitants called Selenites studying astronomy? The fiction story imagined by Kepler was strongly consolidated by astronomical data (scientific footnotes are more numerous than the text itself) and lunar habitability was discussed with scientific arguments. But this book was more a support of the Copernican theory than a convincing demonstration of the plurality of worlds.

The second part of the seventeenth century led to accept the plurality of worlds with less and less hostility from a scientific viewpoint as well as a popular angle, in spite of a continuous reluctance from the Roman Catholic Church.

The first writing attempting to be liberated from this religious ascendancy came from the French philosopher Bernard le Bovier de Fontenelle (1657–1757). He published his *Entretiens sur la pluralité des mondes* (*Conversations on the Plurality of Worlds*) in 1686 which soon became very popular. In spite of this success, the book was still regarded as dangerous by the Roman Catholic Church, which placed it on the Index of Prohibited Books in 1687.

The book presented a series of conversations between a gallant philosopher (Fontenelle himself) and a Marchioness and looked like a didactic entertainment about astronomy. The central question was dealing with the differences between the inhabitants of each planet, according to its proximity to the Sun. Fontenelle populated all the planets of the solar system and the Marchioness was at the same time filled with wonder and overwhelmed in front of this "unlimited number of inhabitants likely to be on all these planets." She was also dubitative when she asserted, "it's a lot of ignorance based on very little science." How can we imagine these planet dwellers so various indeed, if nature is opposed to repetitions, questioned the Marchioness? Fontenelle enjoyed himself imagining that differences increased as the planets became more and more distant from the Sun. But he spent very little time on the case of ► [Mars](#), a planet which seemed to be very similar to the Earth. According to him, Mars had nothing special and it was not worth mentioning it.

Eventually, Fontenelle offered to the reader a very broad plurality of living worlds and its merit is to have been the first to popularize in a pleasant style the idea of diversity of life in the universe.

At the very end of this century, the Dutch physicist, mathematician, and astronomer Christiaan Huygens (1629–1695), who discovered the largest moon of ► [Saturn](#) (► [Titan](#)), worked on a philosophical treatise entitled *Cosmotheoros* (or *Treatise on the Plurality of Worlds*), posthumously published in 1698. This essay dealt with the consequences of the Copernican system and proposed a model for the construction of the universe. Every star was considered as a world with other possible forms of life. Huygens speculated on the habitability of the solar system and thought that the other planets were the abode of creatures quite similar to those living on Earth. The differences were supposed to come, as for Fontenelle, from the more or less great distance from the Sun and its influence on planetary solar heating.

One of the most significant centuries about the question of the habitability of the solar system was the nineteenth century. Developments in planetary observation, especially the first publications of

maps of the Martian surface, built a new scientific field named *areography* (or Martian geography). The surface of Mars was supposed to be covered by oceans and continents (the darker regions were assumed to be seas and the lighter parts continents). This planetary world, which seemed to be very similar to ours, appeared to be a very good candidate to be the abode of life.

The British astronomer Richard A. Proctor (1837–1888), famous for having produced one of the earliest maps of Mars in 1867, wrote many popular books. Among them, *Other Worlds Than Ours*, *The Plurality of Worlds Studied Under The Light of Recent Scientific Researches*, published for the first time in 1870, immediately attracted attention not only of the scientific world but also of a very wide audience. Proctor used a poetical description to show what astronomy taught us about the Sun and its planets and discussed the probability that other worlds could be inhabited. According to him, habitability would be the key argument able to answer the question of the possible life forms on other planets. Habitability could be defined in considering analogies with the Earth, i.e., parameters resembling those existing upon our planet.

Proctor studied the habitability of every planet of the solar system. He suggested that the existence of organized forms of life depended on the conditions supposed to have an effect on the planetary surface, such as climate, seasons, atmosphere, geology, and gravity. For instance, the physical conditions of Venus seemed to show very close resemblances to the terrestrial ones. Arguments coming from analogy allowed him to conclude that this planet could be inhabited.

But it clearly appeared that the best candidate to be the abode of life was ► [Mars](#), “the miniature of our Earth” said Proctor. With seasons equivalent to terrestrial ones, water vapor in the atmosphere, and forms of vegetation growing abundantly (these last points were supposed to be possible), Proctor’s Martian world was perfectly fitted for complex life.

Proctor admitted also life on ► [Jupiter](#). This giant planet might be inhabited by “the most favored races existing throughout the whole range of the solar system,” thanks to the very

symmetry and perfection of the Jupiterian system. He attempted to imagine what kind of forms of life could populate this huge planet. However Proctor wanted to stay under the control of exact knowledge. He thought we could only claim that “the beings of other worlds are very different from any we are acquainted with, without endeavoring to give shape and form to fancies that have no foundation in fact.”

Numerous writings dealing with the habitability of ► [Mars](#) were proposed during this century, especially after the canals controversy launched in the 1880s following Schiaparelli’s observations. Among the most prolific writers on that topic, the French astronomer Camille Flammarion (1842–1925), who founded the Juvisy Observatory (France) in 1883 and the *Société Astronomique de France* (SAF) in 1887, was well-known for his *Pluralité des Mondes habités* (Plurality of Inhabited Worlds) published in 1862, when he was only 20 years old. This book, translated in many languages, explained the conditions of habitability of earthlike celestial bodies discussed from the astronomical, biological, and philosophical viewpoint. A comparative study of the planets of our solar system led him to state that “the Earth was, considering its physical characteristics, a planet of medium kind, without anything remarkable.” Following this idea, life would have been present everywhere in the solar system.

He studied the habitability of the planet Mars while the Martian canals controversy was still running. He published *The planet Mars and its conditions of habitability* (first tome in 1892 – second in 1909) in which he presented the whole collected observations about the surface of Mars and its possibilities to be the abode of life. According to Flammarion, the planet Mars was a “living world” in which the climate and the supposed surface characteristics (seas, canals, continents) offered enough analogies with our planet to authorize the existence of living species not so different from the terrestrial ones. He was very concerned by the canals hypothesis but remained cautious as regards its interpretation.

As a final point, spectroscopic methods were developed by astronomers such as Janssen (1824–1907) or Huggins (1824–1910) during the

end of the nineteenth century and gave new parameters related to habitability and led to reconsider the question of life elsewhere in the solar system.

Definition

Life Support Systems encompass all technologies and processes which enable human presence and activity in space environment.

Overview

Mastering Life Support Systems (LSS) technology is a prerequisite for future sustainable human space exploration by guaranteeing a minimal

dependency from Earth of Lunar and Martian outposts. Various LSS based on physiochemical or biological approaches are or have been under development to convert waste elements to resources that can be used by crew members. The goal of Closed Ecological Life Support Systems (CELSS) based on living organisms and physical-chemical processes is: (i) production of O₂ and biomass with high nutritional value; (ii) use of light as a source of energy for microbiological and plant biosynthesis; and (iii) limited O₂ consumption. This should be achieved with the development of reactor allowing the reconversion of waste, CO₂, and minerals in simplified recycling steps, by using preferentially, well-characterized organisms that possess a certain degree of “space robustness” (Wheeler 2019).

An example is the Micro-Ecological Life Support System Alternative (MELiSSA) program of ESA, which is aimed to develop a CELSS that will provide fresh food, oxygen, and potable water from organic and inorganic waste recycling during long distance space exploration (Lasseur et al. 2010). The MELiSSA project was started in 1989 and has advanced knowledge and understanding of regenerative systems leading to a fully closed loop system. The loop is made up of four compartments with the crew members at the center. The first compartment is the liquefying one that collects the mission waste (i.e., urea, kitchen waste, etc.) as well as the nonedible parts of the higher plant compartment (i.e., straw and roots) and anoxically transforms the waste to ► [ammonium](#), H₂, CO₂, ► [volatile fatty acids](#), and minerals. Then, the photoheterotrophic compartment eliminates the terminal products of the liquefying compartment, and it is followed by the nitrifying compartment that produces nitrates used as nitrogen source by the higher plants and the cyanobacterium *Arthrospira platensis*, e.g., the photoautotrophic compartment regenerates oxygen and produces food.

To date, a stable environment has not been achieved in ground-based demonstrators and test beds developed in various countries [e.g., Russia’s BIOS-1, 2, 3, and 3 M, NASA’s Bioregenerative Life Support Systems Test Complex (BIO-Plex),

Japan's Closed Ecology Experiment Facility (CEEFF), and Biosphere-2 in the USA (Escobar and Nabby 2017)]. Until now, many CELSS containing different types of biological elements (e.g., microalgae, higher plants, fish, and microorganisms) have been proposed.

In this context, the EDEN ISS project has proven the feasibility of a space greenhouse realized in Antarctic, which could also be used on the Moon and Mars, in order to locally grow food by using nutrient delivery, LED lighting, biodegradation and decontamination systems, food quality, and safety procedures as well as operation procedures for safe food production (Zabel et al. 2015; Meinen et al. 2018).

Basic Methodology

LSS are made of elements (systems, subsystems) whose technologies and processes enable human presence in space, and they cover the following key functions: (i) Atmosphere revitalization, e.g., CO₂ removal, O₂ generation, chemical/microbial/physical contamination monitoring and control, and environmental control (temperature/pressure/humidity); (ii) Water recovery and recycling, e.g., collection, processing, and quality control (microbial, chemical); (iii) Food production and preparation, e.g., food production, transformation and storage, and quality control; (iv) Waste recovery and recycling, e.g., collection, storage, and processing of organic wastes generated during the mission; and (v) In situ Resource Utilization (ISRU), e.g., extraction and processing of local resources for Environmental Control & Life Support Systems (ECLSS).

Key Research Findings

The cyanobacterium *Arthrospira platensis* was loaded into a photobioreactor onboard the International Space Station, and for a month the microorganism converted the light into energy, producing oxygen as a byproduct at the same speed as it would on Earth.

Applications

LSS to support human exploration of deep space encompasses numerous technological developments that are also crucial elements for tackling terrestrial challenges such as environment, water, food, safety, ecosystems, circular economy, health, and toxicology (Nelson et al. 2003).

Future Directions

The European Space Agency (ESA) has proposed a short-to-medium horizon mission scenario with the following destinations: Low Earth Orbit (LEO), the Moon (including lunar vicinity), and Mars. In the short term, the ISS will be used as a test bed for closed LSS technologies, mainly for CO₂ removal, water recovery, food production, and waste collection treatment. These activities are part of ECLSS, and systems and subsystems will be used on the Gateway, a NASA human-tended facility placed in the lunar vicinity, which in the medium term will support crew members for 30–40 days. Hence, LSS envisaged mainly technologies for water and atmosphere management that could be tested along with risk management protocols, in relative proximity to Earth in case of an emergency. On the one hand, technologies for waste management, food production, and ISRU are not required in future Moon Surface Operations where LSS could operate in either open- or closed-loop systems. On the other hand, ISRU-based technologies could be exploiting to link LSS to resources available on the ground by using extreme-tolerant cyanobacteria (Verseux et al. 2016). In the long term, LSS technologies validated at the Gateway will be used to support human outposts on Mars, where there will be the need for atmosphere and water revitalization, waste management, food production, and recycling as well as technologies based on ISRU. ISRU implies not only the water recovery but also the potential exploitation of regoliths to support the microbial photosynthesis, or as substrate for plant growth (after physicochemical and/or biological treatments) or as shielding material.

Definition

The concept of life has through the ages been defined in many various ways, each focused on specific characteristics that have been connected to something, whether physical or non-physical existence or process, that sustains life and that humans understand or interpret as constitutive for something being alive (Bognon-Küss and Wolfe 2019; Hall 1969; Tirard et al. 2010; Toellner 1980; Wolfe 2018). The concept of life is inextricably linked to a changeable world and the world-views and self-understanding of the human being. The biological concept of life is thus connected to philosophical, theological, cultural, societal, and political concepts of life.

History

The English word “life” has a Proto-Indo-European root, *leip-, meaning “to stick, adhere.” The

word is thus connected to “continuance, perseverance,” and “to live” then literally means “to continue, remain.” The same root is also the source for the Greek *liparein* “to persist, persevere” and *lipos* “fat,” Old English *lifer* “liver” (the secreting organ) and *læfan* “to allow to remain.” In Greek philosophy, there are two words for “life,” βίος (*bíos*) and ζωή (*zōē*). The former – that we find in words such as “biology” and “biography” – is associated with human life, particularly longevity and way of life. The latter word rather denotes the reality of life whether it concerns humans, animals, or plants. The Latin word “*vita*” encompasses the meaning of both these two Greek words.

In general, ancient philosophers made no distinction between being alive and having a soul. In the pre-Socratic philosophy, Thales, Anaximenes, and Heraclitus argued that all matter can in some respect be considered living, a notion known as *hylozoism*. Plato described life as an inner force of movement. The living is thus something with the ability for self-movement. And this capacity for self-movement is the soul. The ancient philosopher who delved most deeply into the question of what life is, about its various life forms and functions, was Aristotle in the fourth century BCE. In *De anima* (On the Soul) he identifies the soul as the principle of living beings (Aristotle 1986). He distinguishes between lifeless matter (*hyle*) and life as *entelechy* (*entelécheia*), or in other words that which has its purpose in itself and is a realization of a potential possibility. In Aristotle’s view, to be alive is to have a soul, which applies to humans, as well as to plants and animals. The soul is thus the body’s form (*eidos*), which means that when the soul (the form) leaves the body, the body therefore ceases to be alive. The plants have a vegetative soul that allows for growth and reproduction, the animals have a sensitive soul that allows for movement and sensation, while the human being alone has a rational soul that allows for thought and reflection. The Aristotelian doctrine of life dominated in medicine and biology for 2,000 years, with some modifications by, among others, Galen’s physiology and Theophrastus’s studies of plants.

Neoplatonism identified life with motion, as something changeable and unlimited. Life was

the mediating link between being and thinking. Neoplatonic philosophy was not least important for the Christian concept of life. John Scotus Eriugena in the ninth century CE specified four kinds of life on a scale from the higher to the lower, the *vita intellectualis* of angels, the *vita rationalis* of human beings, the *vita sensualis* of animals, and the *vita insensualis* of plants. Hugh of Saint Victor in the twelfth century distinguished two kinds of life, the earthly and the heavenly, one bodily and the other spiritual, one through which the body lives by the soul, the other through which the soul lives by God. During the Middle Ages, the active life, *vita active*, was set against the contemplative life, *vita contemplativa*. The scholastic and Dominican brother Thomas Aquinas gave the latter precedence. For Thomas Aquinas, life had its origin in God, and accordingly, no human being then has the full right to rule alone over his life. Human life is sacred and inviolable.

In medieval medicine, pieces of advice were given on how to preserve and prolong one’s life and health, based on a Hippocratic-Galenic humoral pathology and its identification of the four body fluids. During the sixteenth and seventh centuries, life was associated with the transformations of matter and the influences of the heavens, alchemy, and astrology. In astrology, the world was seen as a system of correspondences or connections. What happened in the heavens thus affected life on Earth. For the influential physician Paracelsus, heaven ruled earthly life in both theological and cosmological-astrological terms. The metals, according to Paracelsian alchemy, were born in the veins of the Earth of sulfur, mercury, and salt, and are multiplied by the heat of the Earth and the influence of the heavens. Stars, comets, eclipses, and other celestial bodies, according to this micro-macrocosmic worldview, had a concrete influence and impact on earthly life.

Life was commonly up to the scientific revolution, understood in accordance with an Aristotelian conception, life as having a soul, life as animation. Pierre Gassendi, for example, wrote in 1658 that “Life corresponds to the presence of the soul in the body, and death to its absence.” A standard conception of life from the Antiquity

to the eighteenth century, particularly in Galenic medicine, was the *pneuma* theory or the theory of animal spirits (*spiritus animalis*). The theory of animal spirits rests on the observation of life as associated with heat and breathing, while the dead body as something cold and immobile. With inhalation, a living principle, “spirits,” is adopted, which made the blood healthy and alive. There were, according to this theory, three kinds of “spirits” (equivalent to “*spiritus*” in Latin or “*pneuma*” in Greek). The natural spirit (*spiritus naturalis*) originates from the abdomen, a fine mist that is born in the liver and spreads through the blood vessels throughout the body. The vital spirit (*spiritus vitalis*) from the chest spreads through the arteries and makes the body lively. The heart is the source of heat and the vivid fluids, the origin of the veins, and the first cause of breath and pulse. And finally, the animal spirit (*spiritus animalis*) from the head, which is the finest and purest mist of the living spirit that is carried up to the brain and then spreads through the nerves throughout the body.

The natural philosopher René Descartes used the concept of *spiritus animalis*, but dressed it in mechanistic terms and explained it as something like “a very weak wind” or a pure, lively steam, which rises from the heart to the brain, then out through the nerves and sets the muscles in motion. Life as “spirits” came, however, during the latter part of the seventeenth century and the first half of the eighteenth century to be overshadowed by the idea of life as motion. The mechanistic concept of life did not describe life as something necessarily animated, but in short just as matter in motion. The new medicine of the scientific revolution, with William Harvey’s explanation in 1628 of the circulation of blood in the human body, came to emphasize the circulatory system as a characteristic feature of living things, as in the blood circulation, the respiration, the circulation of nutrients in the blood, and the sensory circulations of animal spirits through the blood and nerve fluids. Furthermore, Santorio’s quantitative experiments described nutrition and the life processes in terms of measure and weight. Crucial was not least Descartes’ mechanistic philosophy of nature which explained the living body as an extended substance, *res extensa*, that could be described in

geometrical and mechanical terms. Animals were automata and human bodies only matter in motion. However, the mechanical explanation of life had difficulty in explaining the body’s ability for self-movement, and how the interaction between body and soul could take place.

In *L’Homme* (Treatise on Man) from 1633, Descartes described the body as a system of pulleys, funnels, sieves, pipes, bellows, and other mechanical instruments. In a similar, but even more elaborate way, Hermann Boerhaave in *Institutiones medicae* (1708) described the solid part of the human body as pillars, props, axes, wedges, leavers, pulleys, cords, presses, bellows, sieves, strainers, pipes, etc. It was not that the bodily organs were such machines, instead they all, both the natural and the artificial machines, followed the same mechanical laws. According to this mechanistic explanatory model for the life processes in medicine, the so-called iatromechanics, it was motion that constituted life. Hobbes, in this reductionist mode, identified life with the motion of limbs. Robert Boyle insisted that the living body is a kind of hydraulico-pneumatic machine, where the vital fluids and motions differ the living from the dead body, but both were arrangements of same universal kind of corpuscular matter. According to Archibald Pitcairne, “Life consists in the Circulation of the Blood produced by the Motion of the Heart and Arteries.” Boerhaave, as well as the physician Friedrich Hoffmann, life was motion, and death was rest. Life, Hoffmann argued in 1729, consists in the circular motion of blood and body fluids, and death is stagnation, the cessation of movement. Iatromechanical understanding of what life is, was based on the dichotomy between the living and its opposite death, where the former stands for something in motion, is warm and breathing, while the latter is something immobile, cold, and not breathing. The most extreme exponent of this mechanistic view was Julien Offray de La Mettrie claiming that man was just a machine, and the soul as inseparable from the body.

Georges Louis Leclerc, Comte de Buffon identified life in his *Histoire naturelle* (1749) with certain “organic molecules” that were consumed by the organism and gave rise to the vital activity of living things (Tirard 2010). The living differs from the non-living, according to Denis

Diderot, due to just a difference in sensibility, in the activity or inactivity of the particles. Two distinctive capacities of living beings crystallized in the debate concerning the essence of life in the eighteenth century: life as the ability to move or life as the ability to feel.

During the last decades of the eighteenth century, vitalist conceptions of life came to dominate. For the mechanistic philosophers, life could merely be explained in chemical and physical terms. The vitalists, on the other hand, argued that chemical and physical properties were insufficient to describe and explain what life is. Instead, they assumed the existence of a necessary, essential vital force, a principle of life, as the explanation for the bodily processes and self-preservation, and in general the difference between a living and a dead body. The idea of vitality, the theory of vitalism, is thus linked to a longer tradition of life as the ability to self-movement. For Immanuel Kant, life was the ability of a substance to act and change based on an inner principle. Romantic philosophers, such as Friedrich von Schelling, understood life, a living being, as having an inner principle of self-movement. For Arthur Schopenhauer, the will to live was the universal drive of life. Life, Xavier Bichat claimed, is the total sum of functions that resist death. This life force governs organic life. Vitalist conceptions of life dominated biology until the middle of the nineteenth century.

Studies of the living and the life processes, the origin, course, and end of life, as well as the classification of life forms and their essential properties were performed in the seventeenth and eighteenth centuries without necessarily summarizing it in a science of the living, a general life science (Nachtomy and Smith 2014). Through the microscope, one discovered that every drop of water was full of life. Antonie van Leeuwenhoek, Robert Hooke, and other microscopists saw a countless number of microorganisms in this microcosmic world beyond the ordinary sight. A classic question concerned spontaneous generation, *generatio spontanea* or *generatio æquivoca*, that is, the extent to which living organisms can arise spontaneously from dead matter. Flies and larvae seemed to crawl out of rotten meat as if coming from nothing. Fungi grew from the soil, and frogs from swamps. In the

1740s, Abraham Trembley experimented with the freshwater polyp and demonstrated its ability to regenerate by division. Through experiments by John Needham and Lazzaro Spallanzani, later by Louis Pasteur and John Tyndall, the theory of spontaneous generation could finally be rejected, and the discovery of microbes led to modern microbiology.

Another central issue in the life sciences during the eighteenth century, in which Carl Linnaeus made important contributions, concerned the classification and systematization of life. Nature exhibited a variety of life forms. This chaotic diversity could, however, be arranged and named in accordance with the binary nomenclature and the division of nature into kingdoms, classes, orders, genera, and species. The classification and categorization of life was set in an all-encompassing system in Linnaeus's *Systema naturae* (1735) and subsequent editions.

The anatomy and physiology of the seventeenth and eighteenth centuries mapped the living body. In the late eighteenth century, there were several competing medical systems, such as humoral pathology, the Hippocratic-Galenic doctrine, iatromechanics, vitalism, Hoffman's tonus, Stahl's animism, Haller's irritability and sensibility, and many more. Many discoveries during the late eighteenth and early nineteenth centuries changed the view of what life is. Following the discoveries of Carl Wilhelm Scheele, Joseph Priestley, and Antoine-Laurent de Lavoisier, the function of oxygen in respiration was demonstrated. Luigi Galvani and Alessandro Volta demonstrated the muscle electricity. In the 1780s, Galvani did some experiments on frogs showing that the frog legs began kicking when they were exposed to electricity. This could be interpreted as there was a kind of electricity within the living animal, an "animal electricity," a vital force that endowed organic matter with life. Mary Shelley's famous novel *Frankenstein* from 1818 was inspired by the demonstrations of Galvani. A dead human corpse was brought to life by the application of electricity. Other important advances of science that change the conception of life were the discovery of microorganisms, and in its turn the establishment of microbiology and bacteriology as scientific disciplines, as well as Matthias Schleiden and Theodor Schwann's

development of cell theory which identified the cell as the basic unit of life, Karl Ernst von Baer's comparative embryology and the emergence of life from preformed structures, Georges Cuvier's paleontology, Jean-Baptiste de Lamarck and the evolution of life, demonstrating how new species are arising from old, extinct species. According to Lamarck, life could be defined as a certain organic movement that could be activated by an external cause, such as caloric (heat) or electricity. The spontaneous generation of the simplest living beings, he explained as an agitation of matter, the "l'orgasme vital," of subtle gelatinous matter (Tirard 2010).

A collective concept for the study of the living does not emerge however until around 1800, "biology," from the Greek *bios*, life, and the affix *logia*, doctrine, among others by Karl Friedrich Burdach, Gottfried Reinhold Treviranus, and Lamarck. During the latter half of the nineteenth century, the question of life came to be shaped by the new evolutionary biology, Charles Darwin's work on the origin of species, the selection theory and phylogeny. The evolutionary theory explained, even though Darwin lacked an explicit definition of life, how current life forms evolved from previous simpler forms. Darwin even ventured to an explanation of the origin of life from the primordial soup in Earth's early history. Ernst Haeckel put forward the basic biogenetic rule, about ontogeny as a recapitulation of phylogeny, how a human fetus during fetal development seems to undergo the same phases as during the evolution from simple organisms, over fish to mammals.

Overview

In its original sense, life is persistence, perseverance. Implicit in many of the philosophical and biological conceptions of life is the view of life as binary, life and death, warm and cold, and motion and immobility. Commonly one has identified life with certain organs, the heart, the lungs, or the brain, as something existing, something material, with chemical, essential properties, such as organic molecules, and in contrast to that, as a process, something that moves, changes, is becoming something, through fermentation, vital heat, or motion. Life has thus

been conceptualized mainly in two ways, as existence or process. Life has been seen as a mode existence, a state, or an activity, a vital force for self-motion, self-creation, and self-preservation. These concepts of life have given rise to philosophical and scientific questions concerning the essence of life, its material components, its characteristics and description, order and classification, and questions concerning the processes of life, what sustains life, its causes and transformations, its origin and future, and its possible existence elsewhere in universe (Dick 1982; Dick 1996).

Life, Definition of

Erik Persson
Lund University, Lund, Sweden

Definition

There have through history been many attempts to define “life” but there is no generally accepted definition of “life” at this date. As a result, some have come to believe that defining “life” is not a fruitful endeavor. This seems to be a minority view, however, since the quest to find or create a definition of “life” is as active as ever.

Overview

The purpose of defining “life” varies, but the most common purpose is to find a *de re definition* that identifies a *natural kind*.

A natural kind is a grouping of phenomena according to demarcation lines that exist objectively in nature independently of us and can (in theory) be discovered by us, in contrast to a grouping that does not exist independently in nature and thus has to be invented by us.

A *de re* definition is sometimes also called a *real definition* and is contrasted with, for instance, *stipulative definitions* and *operational definitions*.

The purpose of a stipulative definition is to create a definition for a special purpose without

regard for whether the definition refers to any natural kind. Stipulative definitions can be used to define “life” in special situations but are probably not very useful for defining “life” in astrobiology, where life is the primary study object. Given that astrobiology’s ambition is to increase our knowledge about the real world, “life” should reasonably refer to a natural kind, not a grouping created by us for some particular purpose.

The purpose of operative definitions is basically the same as for stipulative definitions, but with the constraint that the definition is based on a particular method, instrument, or the like. It has, for instance, been suggested that different disciplines could define life in different ways. This does not come through as a suitable solution for astrobiology, however, partly because astrobiology is a multi-disciplinary project where the arguably most important term has to refer to the same thing for everyone involved, and partly because the study object of astrobiology is life in a very wide sense that covers the origin, evolution, and future of life on Earth as well as in the universe.

A *de re* definition typically takes the form of a list of properties that are supposedly individually necessary and jointly sufficient to identify the phenomenon in question, in our case, life. That is, each of the properties on the list needs to be shared by all life while no non-living entity can possess all of the properties on the list. It may seem surprising that no one has yet managed to compose such a list. One possible reason for why this is the case, is that we still only know about one instance of life, namely life on Earth, which is all related. This limitation makes it very hard to come up with a general definition of life. Another reason seems to be that life is constantly evolving, which means new properties emerge constantly, while other properties disappear. Life is in that way a moving target and given what we know today about life and evolution, we have no reason to believe that there are any core of properties (also called an *essence*) that is exempt from this process. Even so, many continue to search for one and hope that improved knowledge about life (including a discovery of extraterrestrial life) will reveal such a core of unchangeable properties. Others look for alternative ways of defining

life that are more flexible and do not assume a core of unchangeable properties.

One alternative form of definition is called an *ostensive definition*. An ostensive definition is performed by providing examples of the phenomenon that is to be defined. One can, for instance, point at a number of chairs and say for each of them, “that is a chair.” When confronted by other possible chairs we are then supposedly able to tell if they are chairs or not based on our experience of previous chairs. This is a type of definition that may work well for chairs but that is probably not of much use for a multi-faceted phenomenon like life. It may, however, be historically important as an explanation of how our forefathers started to distinguish between life and non-life. Likewise, it can have pedagogical value as a way of teaching children to distinguish between life and non-life.

Another alternative is the *list definition*. A list definition is provided by listing all the phenomena we want to include under our definition. This is, for obvious reasons, impossible to do with life. There is just too much life. Also, new life is born and old life dies off faster than we would have a chance to update the list. Finally, we can only include life that we know on the list. Life that has not yet been discovered, on or off Earth cannot be included, and even if we do discover extraterrestrial life, we will probably never be able to discover all non-extraterrestrial life. The list can therefore never be complete, and we will thus never have a complete definition of life.

Both the ostensive definition and the list definition can be seen as examples of “I-know-it-when-I-see-it” definitions. Though attractive in the sense that they provide a way of producing a definition without the need for identifying any core properties, there are also some important drawbacks. The most important drawbacks of “I-know-it-when-I-see-it” definitions for astrobiology are probably that:

1. They will not help us determine the tricky cases, that is, discoveries that are not obviously life, nor obviously non-life.
2. They will not help us search for extraterrestrial life. It will be very difficult to determine which experiments, instruments, etc. to choose if we do not know beforehand what we are looking for.

There are also some new alternative suggestions for how to define “life” as a natural kind without having to assume a core of unchangeable properties. These include, for instance, suggestions inspired by Ludwig Wittgenstein’s ideas of *family resemblance*, and Alan Turing’s ideas of how to test for Artificial Intelligence (the so-called *Turing test*). Because they are still not fully developed or tested, it is too early to assess these methods at this date.

Life, Value of

Erik Persson
Lund University, Lund, Sweden

Definition

The phrase “the value of life” can refer to, among other things, the value of life as a phenomenon, the value of particular life forms, the value of individual organisms, or the value of being alive. When used in connection with astrobiology, “the value of life” usually refers either to the value of life as a phenomenon or the value of a particular life form such as extraterrestrial life or a particular species of extremophile.

Overview

Value, whether of life or of other things, comes in many different forms. It is, for instance, common to distinguish between instrumental value and end value (also called final value, intrinsic value, or noninstrumental value) where the former refers to the value something has as a means for promoting something else that has value, while the latter refers to the value something has as an aim in itself, independently of whether it can also promote other values. End value is sometimes described as the final stage in a chain leading up to one or more ultimate values. What “ultimate” means in this sense is debated. Some argue there can only be

one ultimate value, and thus only one phenomenon that has value as an end in itself. This position is known as value monism. Happiness is a common candidate as the one ultimate value according to this position. If that is correct, life can only have instrumental value as being (presumably) a necessary condition for happiness. The opposite position is called value pluralism, and it states that there is no reason why there cannot be more than one end value. Typically, this position considers end value to be subjective and determined by the preferences of individual sentient beings, while others claim that even though there can be more than one phenomenon with end value, some things are suitable as having end value but others are not.

A basic tenant of astrobiology is that life has epistemic value, meaning that life can be used to forward the production of knowledge. The epistemic value of life is therefore a form of instrumental value. The knowledge achieved in this way can in turn be seen as having value in its own right (end value) or as a means to other things (instrumental value), for instance, helping us becoming better stewards of the living environment on our own planet.

It is also common, both among astrobiologists and among people in general, to assign end value to life. This is probably both a strong driving force for astrobiology, and a complicating factor because of the inherent impossibility of studying life without disturbing it in any way (see also the entries on research ethics and planetary protection).

Another common value distinction is that between inherent value (also called intrinsic value) and relational value (also called extrinsic value). The former refers to value that comes from an internal property of the phenomenon with value, while the latter refers to value that comes from some relational property of the phenomenon with value.

In astrobiology, a species can have inherent value, for instance, because of its ability to withstand extreme cold or because of a particularly interesting chemical composition (both inherent properties). If life is found on another planet or moon, it will (in addition to any inherent value it may have) have relational value because it is found on that particular planet or moon. Though some argue that end value can only supervene on inherent properties, it is usually acknowledged

that both inherent value and relational value can also be either instrumental or end value. The value a life form has because it is found on another world (relational value) can be seen as valuable in its own right (end value), and it can also be valuable for its ability to increase our understanding of life in general as well as our understanding of that world (instrumental value). The value a life form has because of its ability to withstand extreme cold (inherent value) is a fascinating fact that cannot only render its value in its own right (end value) but also increase our knowledge about life in general and about the limits for habitability in the universe (instrumental value).

For the question of moral status among living beings, see the entry on astrobioethics.

Institute of Technology, Tokyo, Japan
Blue Marble Space Institute of Science,
Washington, DC, USA
Center for Chemical Evolution, Georgia Institute
of Technology, Atlanta, GA, USA

Definition

In chemistry, a ligand is an ion or molecule that binds to a central metal atom forming what is called a coordination complex, which can be

neutral, cationic, or anionic. The complex, along with its counter ions, is called a coordination compound. The bonding between metal and ligand generally involves the donation of one or more of the ligand's electron pairs. Ligands in an ▶ [organometallic](#) complex often govern the reactivity of the central metal atom.

Ligands that are directly bonded to the metal form the first coordination sphere and are known as “inner sphere” ligands. “Outer-sphere” ligands are not directly attached to the metal but are bonded to the first coordination shell. Heme is an example of a biological coordination complex: the central iron ion is coordinated at the center of a ▶ [porphyrin](#) molecule by the latter's four pyrrole nitrogen atoms.

Light Travel Time Effect

Nader Haghighipour
Institute for Astronomy, University of Hawaii-
Manoa, Honolulu, HI, USA

Definition

The light travel time effect, abbreviated by LITE or LTT (Irwin 1952, 1959), refers to the differences in the periodic mid-eclipse timing for an eclipsing binary star system that is perturbed by an external massive object (e.g., a third star in a tertiary system). For an unperturbed eclipsing binary star system, the two stars of the binary revolve around their common center of mass with a constant period. When the binary system

is perturbed by a third, massive object, the binary's center of mass wobbles around the center of mass of the entire three-body system. This causes the binary to be closer to the observer at times, while at other times, it will be farther away. This wobbling (or reflex motion) of the binary gives rise to time-varying light-travel paths resulting in differences in the periodic mid-eclipse timing for the binary stars. Figure 1 shows a schematic view of a LITE orbit.

Université, Meudon, France

Synonyms

[Light variation](#)

Definition

The lightcurve describes the temporal variation of the brightness of an object.

Overview

The lightcurve shows the temporal variation of the brightness of a celestial body at a given wavelength. Due to the rotation of an object, the lightcurve generally has a sinusoidal periodic behavior with two maxima and two minima. In planetary science, the lightcurve is the most useful tool for investigating the rotational properties and the shape of a body, mainly of small ones: ► [asteroids](#), satellites, ► [comets](#), and transneptunian objects.

Most small bodies cannot be resolved since the apparent angular size of the object is in general smaller than the observer's angular resolution; therefore, analysis of the lightcurve can be used to determine the shape and the surface spots of the observed body.

For an airless body, each point of the lightcurve represents the fraction of the sunlight reflected by the illuminated portion of the body surface in the direction of the observer. The received flux depends on physical (shape, albedo, surface morphology) and geometrical (rotational phase, polar axis orientation) characteristics of the body. All this information can be extracted from a lightcurve by using a well-established inversion technique (Kaasalainen et al. [2002](#)).

The difference between the maximum and the minimum brightness is called the amplitude of the lightcurve and it is measured in magnitudes. The amplitude, however, varies considerably depending on the aspect angle at which the object is observed. It will have, for a given object, the biggest value for an equatorial view and it will be flat (lightcurve with no variation) when the object is observed on a polar view (rotational axis toward the observer). The amplitude of a lightcurve is an indicator of a body's elongation and allows the computation of the axis ratios of the osculating

ellipsoids approximating the shape of the observed object.

The light variations can also be due to the presence of a satellite around the primary body, as well as to complicated rotations, as in the case of tumbling asteroids or active comets. Moreover, seasonal variation of a lightcurve can be produced by activity depending on the heliocentric distance of the observed body. For example, from Pluto's lightcurve, strong evidence for albedo changes over time has been inferred, which is interpreted as a systematic sublimation of frosts from the sunward pole (seasonal variation).

Lightcurve can be also obtained on star occultation by an object of the solar system and can be used to measure the diameter of the body, the existence of an atmosphere, rings, and/or satellites.

In stellar astrophysics, the temporal variation in the brightness of an object such as a variable star or a nova or supernova is also called the lightcurve.

Limb Darkening

Daniel Rouan

LESIA, Observatoire Paris-Site de Meudon, Meudon, France

Definition

The limb darkening phenomenon is a decrease in brightness at the edge (the limb) of the surface of a star or planet. The effect is best studied on the Sun, but has also been put in evidence on other stars. It gives to an image of the Sun the misleading appearance of a sphere illuminated by the observer with a gradual shading on the edge (see Fig. 1). For a star, it occurs because the light at the edge comes on average from cooler – and thus less bright – layers of the ► [photosphere](#). Jupiter also exhibits a limb darkening effect. The limb darkening effect is actually observed when detecting planets by the ► [transit](#) method and must be taken into account to derive the proper planet's size (see Fig. 2).

Limb Darkening, Fig. 1 The limb darkening effect is clearly seen on the Sun: the surface brightness decreases toward the outer part of disk

Limb Darkening, Fig. 2 The limb darkening effect modifies the depth of the light decrease observed when a planet transits in front of the disk of a star. The effect depends on the precise trajectory of the planet across the disk, as illustrated by the two cases

separates the dayside from the nightside: e.g., the moon's crescent is bounded by the limb on one side and by the terminator on the other.

Limb, Astronomical

William M. Irvine

University of Massachusetts, Amherst, MA, USA

Definition

In astronomy, the limb of an object such as the Sun, a planet, or a satellite is the object's apparent edge as seen against the dark sky background. The solar ► "[limb darkening](#)" refers to the fact that the Sun is less bright (because of ► [radiative transfer](#) effects) toward its edge than toward its center. The limb may be compared to the "terminator." For a planet or satellite that is not observed at zero phase angle (i.e., at full phase), the terminator is the locus of points on the object where the line to the Sun (or other source of illumination) is tangent; it thus

Lindblad Resonance

Sean N. Raymond

Laboratoire d'Astrophysique de Bordeaux,
CNRS, Université de Bordeaux, Bordeaux,
France

Definition

Lindblad resonances are the source of spiral density waves in disks. For the case of a planet orbiting a star within a ► [protoplanetary disk](#), Lindblad resonances are found at the location where the disk's natural epicyclic frequency (the frequency at which a radially displaced fluid parcel will oscillate) is a commensurate multiple of the planet's orbital period. This is the same case as for mean motion resonances, but altered by pressure support in the gaseous component of the disk. Density waves triggered at inner and outer Lindblad resonances act, together with matter in the co-orbital region, to torque the planet's orbit and lead to (type 1) orbital migration for planets with masses between roughly 1 and 50 Earth masses.

Lindblad resonances are postulated to drive spiral density waves in galaxies.

Line Shielding

Steven B. Charnley
Solar System Exploration Division, Code 691,
Astrochemistry Laboratory, NASA Goddard
Space Flight Center, Greenbelt, MD, USA

Definition

Line shielding refers to the situation in which molecules whose photo-destruction is controlled by absorption of radiation in spectral lines can have their destruction rates greatly reduced in interstellar clouds. This arises when there is sufficient material between the source of UV radiation and the cloud interior such that molecules in the exterior layers of the cloud preferentially absorb the dissociating photons, thus leading to molecules in the cloud interior experiencing a greatly attenuated photon flux. Line shielding is important for the survival of H₂ and CO in ► [molecular clouds](#) near energetic astrophysical sources.

Linewidth

Daniel Rouan

LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

The expression linewidth designates the intrinsic width of a ► [spectral line](#) expressed in units of ► [wavelength](#) (Å, nm, μm, etc.) or frequency (Hz). Generally, it is the full width at half maximum (FWHM) that is used. The linewidth can refer to a line in absorption or emission. The width of a line results in general from the contributions of several phenomena: for instance, the natural linewidth is linked to the lifetime of the transition, while the Doppler broadening is due to chaotic movements (turbulence, thermal motion)

Linewidth, Fig. 1 The linewidth of the hydrogen H α line seen in absorption in the spectrum of the Sun at $\lambda = 656.6$ nm. The arrows mark the width adopted here (FWHM).

One notes here that the pedestal of the line (top, or bottom in the case of an emission line) can be much larger than the linewidth

in the emitting medium. Note that the spectrograph used to measure a spectral line must have a spectral resolution better than the linewidth to derive a proper value. Figure 1 illustrates the linewidth of a strong hydrogen line ($H\alpha$) seen in the solar spectrum.

Lipid Bilayer

David Deamer
Department of Chemistry, University of
California, Santa Cruz, Santa Cruz, CA, USA

Keywords

Hydrophobic effect · Permeability barrier ·
Self-assembly

Synonyms

[Membrane](#)

Definition

Lipid bilayers are the primary structural components of all biological membranes, serving as a boundary between the cytoplasm and the external environment.

Overview

Self-assembled structures of amphiphilic molecules occur as ► [micelles](#), monolayers, and bilayers. Monolayers form when amphiphilic molecules accumulate as a monomolecular film at the air-water interface. In contrast, lipid bilayers assemble in bulk aqueous phases, consisting of two monolayers associated in such a way that the nonpolar hydrocarbon chains are directed inward, with hydrophilic polar or ionic groups on the outer surface. Because of their nonpolar interior composed of hydrocarbon chains, lipid bilayers are relatively impermeable to simple ions or ionic compounds in solution. This allows them to act as ► [permeability](#) barriers, which in turn permits ion gradients to be produced and maintained by ion transport enzymes.

Lipid bilayers are surprisingly stable, even though the amphiphilic molecules are not held together by covalent bonds. Instead, the associations between lipid molecules are stabilized by the hydrophobic effect that tends to exclude hydrocarbon chains from bulk water. This stability allows

lipids to assemble into microscopic compartments also called lipid vesicles, or sometimes liposomes. The relevance to the origin of life is that self-assembling amphiphilic molecules were likely to be components of the mixture of organic compounds present in the early Earth environment and could therefore provide membranous compartments required for the first forms of cellular life.

Liquid Chromatography-Mass Spectrometry

Shohei Ohara
Carnegie Institution of Washington, Geophysical
Laboratory, Washington, DC, USA

Keywords

Electrospray ionization · Liquid chromatography · Mass spectrometry

Synonyms

[LC/MS](#)

Definition

Liquid chromatography-mass spectrometry is an analytical technique that combines liquid chromatography (LC) as a separation technique with mass spectrometry (MS) as a detection technique.

Overview

Liquid chromatography (LC) is an analytical technique that exploits the fact that different molecules partition to differing extents between a liquid mobile phase and solid stationary phase. LC is used to separate a very wide range of polar and nonpolar compounds, from low-molecular-weight organic and inorganic compounds to high-molecular-weight proteins and nucleic acids. The use of mass spectrometric detection after a chromatographic separation is a particularly powerful combination in the case of the analysis of complex mixtures in which many compounds co-elute and molecule-specific discrimination is required for unambiguous detection and quantification. Mass spectrometry requires the ionization of the eluting molecules (either positively or negatively charged) followed by the acceleration and separation of the subsequently formed ions according to their dynamic response to either a fixed (magnetic sector) or oscillatory (quadrupole) magnetic field or simply as a function of time (time-of-flight) subject to the ionic mass-to-charge (m/z) ratio. One of the greatest challenges in interfacing LC with MS was how to introduce the liquid chromatographic eluant into the low-vacuum environment required for mass spectrometry. The introduction of the atmospheric pressure ionization (API Huang et al. 1990) technique greatly expanded the number of compounds that can be analyzed by LC/MS. In API, aerosol droplets are ionized at the tip of a nebulizer at atmospheric pressure. The carrier liquid is stripped from the droplets by N_2 gas during their passage from the nebulizer tip to the extraction cone of the MS during which time the charge is transferred to the eluting molecule. Common API techniques include electrospray ionization (ESI Fenn et al. 1989) and atmospheric pressure chemical ionization (APCI Horning et al. 1974). ESI is especially useful for analyzing large biomolecules such as proteins,

peptides, and oligonucleotides, where the use of time-of-flight mass detectors allows for the analysis of high-molecular-weight (MW) molecules. However, if tandem MS is desired (i.e., MS/MS), at least one of the mass detectors has to be a quadrupole. During ESI, large molecules often acquire more than one charge; thus, LC/MS with quadrupole mass analyzers can analyze molecules as large as 150,000 amu even though a quadrupole mass detector typically has an m/z upper limit on the order of 3000 (e.g., 150,000 amu/50 z = 3000 m/z). APCI is applicable to a wide range of polar and nonpolar molecules with MW lower than 1500 amu.

Definition

In chemistry, the liquidus is the highest temperature at which crystals can exist in a melt at thermodynamic equilibrium. Above the liquidus temperature, the material is homogeneous; below it, two phases exist as crystals begin to form. Below the liquidus temperature, homogeneous glasses may exist via rapid cooling and kinetic inhibition of crystallization.

Definition

LISA is a joint research laboratory involving two universities in Paris, France, and the French National Center for Scientific Research (CNRS). The principal research area is studying how the terrestrial and other planetary atmospheres function, using direct observation, laboratory simulations, and numerical modeling. In terms of astrobiology, LISA research includes studies of the reactivity and evolution of organic matter in

extraterrestrial environments and the search for organic matter in these environments. LISA uses laboratory experiments to simulate extraterrestrial conditions and participates in the designing and construction of instrumentation for chemical analysis, to be used on space missions (principally for ESA and NASA).

Lithium Absorption

Steven W. Stahler
Department of Astronomy, University of California, Berkeley, CA, USA

Definition

The presence of the element lithium acts as a chronometer for stars and brown dwarfs. Objects of solar mass and below which have lithium in their atmospheres must be relatively young, since the element is eventually destroyed by fusing with protons. The presence of the lithium absorption line at 6,708 Å has often been used to confirm the youth of suspected pre-main-sequence stars. Very low-mass stars and brown dwarfs evolve so slowly and are cold enough that their lithium may be intact even at a substantial age. Thus, the appearance of lithium below a certain mass has yielded the ages of ► [stellar clusters](#) such as the Pleiades.

Lithopanspermia

Gerda Horneck
DLR German Aerospace Center, Institute of Aerospace Medicine, Radiation Biology, Köln, Germany

Definition

The term Lithopanspermia describes a scenario of interplanetary transport of microorganism by use of ► [meteorites](#). It involves three basic steps: (i) the escape process, that is, removal to space of biological material, which has survived being lifted from surface to high altitudes by impact ejection; (ii) interim state in space, that is, ► [survival](#) of the biological material over timescales comparable with interplanetary or interstellar passage; (iii) the entry process, that is, nondestructive deposition of the biological material on another planet. All three steps of lithopanspermia are now accessible to experimental testing in ground simulation facilities as well as in exposure experiments in space.

History

The possibility of meteorite-mediated interplanetary transport of life was already considered in the 1870s by von Helmholtz and Thomson (Lord Kelvin), who favored a version of ► [Panspermia](#) in which fragments of extraterrestrial rocks carrying microbes as blind passengers within their cracks may transport life from one planet to the other. However, during their lifetime, no mechanism was known to accelerate rocks to escape velocities in order to leave their planet of origin; as a result Kelvin's idea was discarded. After the discovery in 1983 that a certain group of meteorites (SNC meteorites) has originated from ► [Mars](#), evidence was provided that rocks can naturally be transferred between ► [terrestrial planets](#) in conditions that could maintain trapped viable life systems, and as a consequence, Kelvin's idea, now called Lithopanspermia, has been revisited.

Lithophile Elements

Francis Albarède

Laboratoire de Géologie de Lyon, Ecole Normale Supérieure de Lyon, Lyon Cedex 7, France

Definition

In the Berzelius-Goldschmidt classification, lithophile elements are those concentrated in the rocky part (lithos) of the terrestrial planets. They bond with oxygen in tetrahedral sites (Si, Al, P) or in octahedral and dodecahedral sites. These elements form either silicates and oxides (Ca, Mg, Fe, Al, Ti, Na, K) or solid solutions in these minerals. Among the metals, the alkali (Li, Na, K, Rb, Cs) and alkali-earth elements (Mg, Ca, Sr, Ba), the rare-earth elements and the actinides (U, Th), and the high field-strength elements (Ti, Zr, Hf, V, Nb, Ta) are broadly used in geochemistry. Halogens (F, Cl, Br, I) also have a lithophile behavior.

Lithosphere, Planetary

Nicholas Arndt

Emeritus Professor, ISTerre, University Grenoble Alpes, Grenoble, France

Definition

The *lithosphere* is the comparatively cold, rigid outermost layer of the Earth and of other rocky planets. It is thus defined by a thermal, not a compositional change. Earth has two types of lithospheres: *Oceanic lithosphere* comprises an upper layer of mainly basaltic crust and a lower layer of mantle peridotite whose thickness increases from a few kilometers at mid-ocean ridges to about 100 km beneath the oldest parts of the oceanic crust. *Continental lithosphere* comprises the continental crust and a section of the mantle whose thickness varies from tens of kilometers beneath active rifts to over 200 km beneath old Archean age cratons such as beneath the Kaapvaal, South Africa. Heat transfer is conductive through the lithosphere but convective in the underlying asthenosphere. Martian lithosphere is around 83 km thick beneath ► [Olympus Mons](#) and other volcanic complexes. The shallow lithosphere of ► [Venus](#) consists of a region of brittle flow in the crust to a depth of 2–4 km, underlain by a weak lower crust and brittle to ductile upper mantle.

Lithotroph

Charles S. Cockell

Geomicrobiology Research Group, PSSRI, Open University, Milton Keynes, UK

Keywords

Inorganic compounds · Electron donor ·
Extreme environments · Lithic habitats

Definition

Lithotrophs are microorganisms that use inorganic compounds as electron donors to conserve energy for growth.

Overview

A lithotroph is a microorganism that uses inorganic substrates as a source of electron donors to drive energy acquisition, using either organic carbon or carbon dioxide as a source of carbon for constructing cellular materials (Ehrlich and Newman 2008). Microorganisms oxidize the electron donors to generate electrons that are channeled into electron respiratory chains to produce the energy-storing molecule, ► [ATP](#). These organisms can use a variety of electron acceptors to complete the respiratory process, including oxygen, sulfate, and other compounds. Lithotroph means rock (lithos) eater (troph) and representatives are found in both the bacterial and archaeal domains. No multicellular organisms are currently known that are able to use inorganic compounds as an ► [energy source](#), although they can gain energy from symbioses with lithotrophs. Examples of lithotrophs include iron-oxidizing ► [bacteria](#) that metabolize reduced iron to oxidized iron, purple sulfur bacteria that transform sulfide into sulfur, nitrifying bacteria that use ammonia and convert it into nitrite or use nitrite to produce

nitrate, hydrogen bacteria that oxidize hydrogen to water, and a range of sulfur bacteria that use oxidized sulfur compounds to produce sulfide (Widdel et al. 1993; Raven 2009). ► [Methanogens](#) are also lithotrophs and use hydrogen to reduce carbon dioxide to methane. The use of inorganic compounds in this way makes lithotrophs important in a wide variety of geological processes including the biogeochemical cycling of carbon, nitrogen, and sulfur, and the weathering of rocks both on the surface of the Earth and in the deep ocean crust, which releases nutrients into the ► [biosphere](#) and is responsible for drawing down carbon dioxide from the atmosphere (influencing long-term climate control) (Bach and Edwards 2003). Lithotrophs are not exclusively associated with extreme environments, but in physical and chemical extremes they tend to dominate. For example, *Thiobacillus* species, which are iron-oxidizing bacteria, are found in highly acidic environments where reduced iron is stable. Their activity in the environment contributes to the well-known phenomenon of acid mine drainage (AMD) (Baker and Banfield 2003), whereby oxidation of iron in ► [pyrite](#) and its further catalytic effect on pyrite oxidation produces sulfuric acid, generating extremely acidic environments in which the organisms thrive. Methanogens are found in the deep subsurface, where hydrogen that is generated by water-rock reactions in ultramafic settings is used as the electron donor (Lollar et al. 2006). On account of their ability to grow in extreme environments, lithotrophs are of great interest to astrobiologists since their ability to use inorganic compounds from rocks, or the products of chemical reactions involving rocks, makes their metabolisms potential analogues for metabolic processes that could sustain life in other planetary crusts (Onstott et al. 2006) and they provide insights into potential lithotrophic conversions on the early Earth (Canfield et al. 2006; Sleep and Bird 2007; Cockell 2010). Lithotrophs can be divided into a number of subgroups. Photo-lithotrophs use light to gain energy, the inorganic

electron donors being used only in biological synthesis reactions. Photolithotrophs are common in anaerobic environments and include the green bacteria (e.g., Chlorobiaceae) and purple bacteria (e.g., Chromatiaceae), which use sulfide, sulfur, hydrogen, and iron as electron donors. The oxygenic cyanobacteria are also photolithotrophs. Lithoheterotrophs gain their energy from inorganic compounds but use organic matter or other organisms as a source of carbon. Lithoautotrophs use carbon dioxide as a source of carbon and mixotrophs are capable of gaining carbon either from carbon dioxide or from organic carbon.

Lomagundi Carbon Isotope Excursion

Andrey Bekker

Department of Earth Sciences, University of California, Riverside, CA, USA

Department of Geology, University of Johannesburg, Johannesburg, South Africa

Keywords

Paleoproterozoic · Lomagundi Carbon Isotope Excursion · Rise of atmospheric oxygen

Synonyms

Lomagundi–Jatuli Carbon Isotope Excursion;
Paleoproterozoic Carbon Isotope Excursion

Definition

The Lomagundi carbon isotope excursion (LCIE), *sensu stricto* (s.s.), refers to highly positive carbon isotope values (on the average +8‰, but values as high as +16‰ are not uncommon with the highest values observed at +28‰) in Paleoproterozoic sedimentary carbonates deposited between ~2.22 and 2.06 Ga (Karhu and Holland 1996; Bekker et al. 2003), likely reflecting open-marine seawater composition. The beginning and the end of the excursion have not so far been observed in the sedimentary record, and there is also uncertainty about the exact age of these transitions. Positive (at ~2.32 Ga and between ~2.45 and ~2.32 Ga; Bekker et al. 2001; Rasmussen et al. 2013) and negative (between ~2.45 and 2.32 Ga; Bekker et al. 2005) carbon isotope excursions have been found leading to the LCIE s.s. The older positive carbon isotope excursions, in particular the ~2.32 Ga one, are considered to be an early expression of the LCIE *sensu lato* (s.l.). Furthermore, a short-lived, large-amplitude ~2.03 Ga carbon isotope excursion after the LCIE has recently been documented in the Woolly Dolomite of

Western Australia that was deposited in the rift basin connected to the ocean (Bekker et al. 2016). Although originally considered to be a plausible cause for the Great Oxidation Event (GOE) (e.g., Karhu and Holland 1996), it is now widely agreed that the LCIE s.s. followed the GOE and potentially occurred in response to it (e.g., Konhauser et al. 2011; Bekker and Holland 2012). The LCIE s.l. is associated with the Huronian ice ages and the final stage in the assembly of the supercraton Superia (Gumsley et al. 2017), while the LCIE s.s. followed them and ended during the sea level rise associated with the supercontinent breakup and submarine hydrothermal activity (Ossa Ossa et al. 2018). The excursion ended up with the ocean deoxygenation event and in association with deposition of Mn- and P-rich sediments (Bekker et al. 2003). This is by far the longest-lived and largest perturbation to the biogeochemical carbon cycle in the Earth's history, and yet, in contrast to Neoproterozoic events, it followed rather than led to the first series of global-scale ice ages.

History

Paleoproterozoic sedimentary carbonates with highly positive carbon isotope values were first discovered by Galimov et al. (1968) on the Fennoscandian Shield (Kola Peninsula and Karelia, Russia). At that time, authors did not recognize global significance of this phenomenon nor related it to a high relative burial rate of organic carbon. Seven years later, Galimov et al. (1975) reproduced earlier observations on a larger set of samples from Karelia and Kola Peninsula and Schidlowski et al. (1975) found similar values in correlative units of the Peräpohja Schist Belt in Finland near Gulf of Bothnia and in carbonates of the Lomagundi Group, Zimbabwe. The following year, Schidlowski et al. (1976) analyzed 67 carbonate samples from the Lomagundi Group, Zimbabwe, establishing for the first-time basin-scale extent of this anomaly and its name. Poor age constraints prevented them from recognizing the global nature of this anomaly, and they opted for

deposition in a closed lake with high productivity. Discovery of the similar-magnitude carbon isotope excursion in roughly correlative, high metamorphic grade carbonates of the Loch Maree Group (Scotland) and Lofoten Vesterålen (Norway) led Baker and Fallick (1989a, b) to propose global extent of this anomaly. Subsequent detailed work on the scale of the Fennoscandian Shield and a comprehensive review of geochronologic and chemostratigraphic data for carbonates bearing the LCIE confirmed the global nature of this signal and bracketed it between ~2.22 and 2.06 Ga (Karhu 1993; Karhu and Holland 1996). The LCIE s.s. has now been discovered on all continents except Antarctica. The older part of the secular carbon isotope curve for the Paleoproterozoic is still poorly constrained since precise ages for carbonates and carbonates themselves are rare for this time interval. Recent work established older than and leading to the LCIE s.s. positive and negative carbon isotope excursions and focused on relationships with other environmental and tectonic changes during the early Paleoproterozoic (e.g., Bekker et al. 2001, 2005, 2006; Rasmussen et al. 2013).

The global nature and sedimentary facies dependence of the LCIE has been discussed numerous times (e.g., Kheiskanen and Rychanchik 1999; Frauenstein et al. 2009; Bakakas Mayika et al. 2020; Prave et al. 2022; see Bekker et al. 2021 for a different view). Specifically, coupling between sedimentary facies and carbon isotope composition of carbonates has been used to argue for heterogeneity in carbon isotope composition of dissolved inorganic carbon in the middle Proterozoic ocean, although opposite trends from shallow- to deep-water settings have been postulated by Kheiskanen and Rychanchik 1999 and Prave et al. 2022. It is difficult to establish synchronicity of shallow- and deep-water facies in Paleoproterozoic sedimentary successions that do not outcrop well. Therefore, Bakakas Mayika et al. 2020 and Prave et al. 2022 relied on the Golovkinsky-Walther's Law, which states that "in a vertical succession of strata unbroken by significant hiatal surfaces, rocks layered one on top of the other were deposited in coeval, laterally adjacent

environments." While this law works well under steady-state sedimentary conditions, it would not work if the surface conditions were perturbed by global or widespread change in redox or chemistry. For example, deposition of black shales during the Cretaceous anoxic events above oxygenated sediments by no means implies that they represent coeval, laterally adjacent environments. Prave et al. (2022) used 100 Ma binning for carbonate carbon isotope data to infer that shallow-marine successions were marked by highly positive carbon isotope values, while deep-water successions were not during the ~2.22–2.06 Ga LCIE. The binning size is, however, too long to make this inference since pre- or post-LCIE successions can be erroneously assumed to be deposited during the LCIE. Presently, there is no known precisely dated LCIE-aged carbonate succession that does not carry positive carbon isotope excursion. It thus seems unlikely that the LCIE is a record of unprecedented seawater heterogeneity in carbon isotope composition of dissolved inorganic carbon, but further work is needed to precisely constrain ages of middle Paleoproterozoic sedimentary carbonate successions that record and do not record the LCIE.

Overview

The rise of atmospheric oxygen in association with the Huronian ice ages led to dramatic fluctuations with escalating magnitude in biogeochemical carbon cycle following the long-term stability of the Archean carbon cycle (Fig. 1). Although these fluctuations are only recognized in single sections, making this part of the secular carbon isotope variation curve less certain, their development before and during the Huronian ice ages argues for a dynamic state of carbon cycle at that time. The negative carbon isotope excursion in cap carbonates overlying glacial diamictites of the second Huronian ice age was recognized in multiple successions in North America and South Africa (Bekker et al. 2001, 2005). However, the subsequent positive carbon isotope excursion, bracketed between two glacial

Lomagundi Carbon Isotope Excursion, Fig. 1 Secular carbon isotope variations in seawater and redox indicators for the oxidation state of the early Paleoproterozoic atmosphere–ocean system (Modified from Bekker and Holland 2012). Four blue vertical bars mark Paleoproterozoic glacial events; the dashed secular carbon isotope curve between 2.5 and 2.22 Ga emphasizes the uncertainty in this part of the curve; red filled shape is the Woolly Dolomite excursion (Bekker et al. 2016); the dashed bar for

marine sulfate evaporites after ~2.06 Ga indicates that sulfate evaporites again became rare in the Paleoproterozoic and Mesoproterozoic records after that time. Deposition of iron formations and Mn-rich deposits indicates anoxic conditions in deep waters. While deposition of iron formations does not necessary require atmospheric oxygen and can be mediated by anoxygenic photosynthetic bacteria, Mn oxidation requires significant levels of atmospheric oxygen

diamictites, so far was only found in the Deutschland Formation of South Africa (Bekker et al. 2001). The 2.32 Ga Gordon Lake Formation of the Huronian Supergroup, Canada, provides a record of the positive carbon isotope excursion preceding the last (fourth) Paleoproterozoic glaciation before the LCIE s.s. (Bekker et al. 2005; Rasmussen et al. 2013). The LCIE s.s. started some time before the 2.22 Ga mantle plume event, but the stratigraphic record of rising carbon isotope values was not yet found. It is thus unclear whether the 2.32 Ga Gordon Lake Formation records the initial stage of the LCIE s.s. or is a separate event, although considering that they are separated by an ice age, it is likely that they represent separate events. The carbon isotope values mostly stayed at around +8‰ for the duration of the LCIE s.s., but it seems there is a rise to higher (~+15‰) values in the middle part of the

excursion with the highest values found at +28‰ (Bekker et al. 2003; Fig. 2). Since the positive C-isotope values are likely to reflect high relative burial rate of organic carbon, large amounts of oxygen must have been released to the surface environments during the LCIE s.s. (cf. Karhu and Holland 1996) with iron and sulfur in the continental crust consuming most of it. Indeed, red beds, sulfate evaporites, and high concentrations of redox-sensitive trace metals such as U, Mo, and Re in organic matter-rich shales appear at that time (but not reaching anywhere close to the Phanerozoic levels; Scott et al. 2008; Partin et al. 2013; Sheen et al. 2018), indicating expansion of oxidized environments in the ocean. Despite high burial rates of organic carbon, coeval Al-rich shales and clean, mature quartz sandstones indicate intense chemical weathering and likely CO₂-rich atmosphere during the LCIE s.s. The fall of

Lomagundi Carbon Isotope Excursion,

Fig. 2 Stratigraphic column, inferred shallowing/deepening upward cycles, and variations of $\delta^{13}\text{C}_{\text{carb}}$ values in the Nash Fork Formation, Snowy Pass Supergroup of Wyoming (Modified from Bekker et al. 2003). Labels to the right of the stratigraphic column refer to members. Note the total thickness and extreme ^{13}C enrichment at the base of the unit

carbonate carbon isotope values at the end of the LCIE s.s. and its stratigraphic expression in the rock record are not yet documented in detail, but the best sedimentary succession for this work might be the Zaonega Formation of Karelia, Russia (Črne et al. 2014). The transition to normal (close to 0‰) carbon isotope values is associated with the sea level rise linked to the supercontinent breakup (cf. Bekker et al. 2003) and therefore marked by a change from carbonate to siliciclastic, organic matter-rich lithologies. Geochronologically, the end of the LCIE is bracketed between 2.11 and 2.06 Ga (Karhu and Holland

1996; Melezhik et al. 2007; Martin et al. 2013); however, the data suggest that it happened closer to 2.11 Ga than to 2.06 Ga. The end of the LCIE is marked by deposition of organic matter-rich shales with highly ^{13}C -depleted isotope values and Mn- and P-rich sediments, whereas sulfate evaporites became again scarce and proxies for ocean oxidation state indicate expansion of anoxia (e.g., Scott et al. 2014). Although Kump et al. (2011) inferred large negative carbonate carbon isotope excursion in the aftermath of the LCIE, the subsequent detailed studies (Črne et al. 2014; Kreitsmann et al. 2019) and the global record

(e.g., Bekker et al. 2003) do not support seawater signal for the reported negative values. At least one younger than the LCIE positive carbon isotope excursions have been demonstrated with the ~2.03 Ga Woolly Dolomite of West Australia (Bekker et al. 2016).

The beginning of the LCIE s.l. has been related to high continental nutrient (e.g., phosphorus) flux linked to acidic groundwaters during the GOE (Konhauser et al. 2011; Bekker and Holland 2012). The highly acidic conditions in terrestrial waters were inferred to be related to extensive oxidation of continental sulfides for the first time during weathering. Acidic conditions in continental runoff promoted dissolution of phosphates and higher P delivery to the ocean resulting in higher relative burial rate of organic carbon and associated oxygen release. The duration of the LCIE s.s. is comparable to the half-life of sedimentary rocks in the continental crust suggesting that groundwater acidity was largely titrated by the end of the LCIE. This, by itself, could have resulted in decreased nutrient (e.g., phosphorus) flux to the ocean bringing the LCIE to the end (cf. Bekker and Holland 2012). Alternatively, weathering of organic matter-rich shales deposited during the LCIE and uplifted during the ~2.1 Ga accretional and orogenic events could have contributed carbon with highly negative carbon isotope values to the atmosphere–ocean system and resulted in expansion of anoxic settings in the oceans (cf. Kump et al. 2011; Bekker and Holland 2012). It remains unclear which of these two scenarios (or both) led to the end of the LCIE. Deoxygenation of the atmosphere–ocean system and collapse of the seawater sulfate reservoir have been indeed inferred (e.g., Planavsky et al. 2012; Partin et al. 2013; Scott et al. 2014; Ossa Ossa et al. 2018). Ocean with a shallow-water redoxcline would harbor secondary productivity, and highly negative carbon isotope values of organic matter deposited in the aftermath of the LCIE suggest methane production and biological recycling. Considering large fractionations between organic and carbonate carbon, evidence for warm climate and moderate levels of pCO₂ during the Middle Proterozoic (Sheldon 2013), it is likely that some of the methane produced in the

ocean escaped into the low-oxygen atmosphere, where it functioned as a short-lived greenhouse gas (cf. Pavlov et al. 2003). In summary, the largest and longest-lived carbon isotope excursion in the Earth's history ended up with the return to low-oxygen levels in the atmosphere–ocean system, intermediate between those during the Archean and GOE.

Definition

The Long Duration Exposure Facility (LDEF) was a large nearly cylindrical structure designed to provide long-term data on the space environment and its effects on space systems and operations. It was transported to space by the Space Shuttle in 1984 and remained in Earth orbit for nearly 6 years until it was retrieved by the Space Shuttle in 1990.

Overview

The Long Duration Exposure Facility (LDEF) was a large open-grid cylindrical structure, on which a series of rectangular trays used for mounting experiment hardware were attached. LDEF was launched and deployed in Earth orbit by the Shuttle Challenger on April 7, 1984, where it stayed in a nearly circular orbit at an altitude of about 500 km and an inclination of 28.4° (Fig. 1). LDEF was attitude controlled, i.e., oriented with respect to a defined frame of reference, with one end always facing Earth and the other one always facing space. This was achieved by gravity gradient and inertial distribution to maintain three-axis stability in orbit. Propulsion or other attitude control systems were not required, and LDEF was free of acceleration forces and contaminants from jet firings. LDEF was retrieved by the Shuttle Columbia on January 11, 1990.

LDEF accommodated 57 experiments, including the following three biological experiments:

Long Duration Exposure Facility, Fig. 1 LDEF structure before release from the arm of the Space Shuttle. Biostack units are accommodated on the space pointing end (upper right corner) of LDEF

- Space Expose Experiment Developed for Students (SEEDS), which carried 12.5-million tomato seeds that after retrieval were offered to students to evaluate their survivability after storage in the space environment and to determine possible mutants and changes in the mutation rate (Hammond et al. 1996).
- Free Flyer Biostack experiment (Fig. 1), which consisted of several ► [Biostack](#) units to study the biological effectiveness of HZE particles (particles of high atomic number Z and high energy) of cosmic rays (Wiegel et al. 1995; Mei et al. 1994; Horneck 1994; Zimmermann et al. 1996).
- Exostack experiment accommodated in two Biostack units facing space, which were open to space (covered by a perforated dome only) to study the long-term ► [survival](#) of ► [spores](#) of *Bacillus subtilis* in outer space. If shielded from the influx of solar extraterrestrial ► [UV radiation](#) and embedded in 5% sugar as a chemical protecting substance, 70–90% of the spores survived the nearly 6-year exposure to outer space on board LDEF (Horneck et al. 1994; Horneck 1998). With LDEF, the longest exposure of microorganisms to space has been achieved so far.

Molecular dissymmetry · Pouchet · Spontaneous generation

History

Louis Pasteur (1822–1895) was a student at the École Normale Supérieure in Paris where he studied physics and chemistry. His scientific work led to important transformations in biology and medicine.

From 1847, Pasteur worked on crystallography. By studying how tartaric acid salts deflect polarized light, he showed that the paratartrate does not have this property because it is made up of a mixture of two symmetrical tartaric acid crystals that can be separated manually under the microscope. In 1854, Pasteur was working at the Faculty of Sciences of Lille. Distillers of the north of France asked him to work on the irregularities of alcoholic fermentation. He showed that a given mold consumed only the right tartaric acid. Pasteur then asserted that living beings are characterized by molecular dissymmetry, because they contain only one of the two forms of asymmetric molecules, for example, left albumin and left quinine. He thus posed a distinction between the living and the nonliving, and he affirms: “I even feel that all living species are primordially, in their structure, in their external forms, functions of the cosmic dissymmetry” (Pasteur 1994).

He also engaged in a scientific debate on the cause of fermentation and claimed that it is necessarily microorganisms. Fermentation is not, according to him, an action by contact, as Berzelius thought, or a spontaneous decomposition of the substance, as Justus von Liebig thought. He developed a process for eliminating the “ferments” by heating. This process called pasteurization will be widely applied to the manufacture of food.

In 1857, Pasteur was professor in the École Normale Supérieure in Paris. At the instigation of the Academy of Sciences of Paris, which launched a prize concerning the existence or not of spontaneous generation, a debate took place in the early 1860s that had a strong impact. Pasteur opposed the biologist from Rouen, Félix Pouchet (1800–1872), who had published a book on heterogenesis in 1859. This debate lasted about 6 years. The two opposing groups criticized their respective experiments. They studied the

possibility of the development of microorganisms in glass balloons containing previously heated organic mixtures. Pasteur used artificial mixtures, and Pouchet used decoctions of heated hay. The first observed the absence of spontaneous generation, whereas the second noted the formation of microorganisms. Pasteur’s conclusion was that the germs observed by Pouchet were either pre-existing in the medium or resulted from contamination by air germs. During the debate, the experimental instruments were modified to answer the arguments of the opposite group. Thus, Pasteur invented his balloons with thin and curved necks to prevent the entry of germs, and the protagonists moved to the mountains to submit the contents of their balloons to air that, according to Pasteur, would contain fewer germs in altitude. As for Pouchet’s hay decoctions, it would later turn out that they contained heat-resistant *Bacillus subtilis* spores, which he could not know, but which finally explains his results and his apparent spontaneous generation.

This scientific debate had an important impact in France. It opposed two communities, Pasteur’s camp being in fact the most conservative, and his opposition to spontaneous generation was not without a certain rejection of evolutionism.

In addition to these fundamental aspects, Pasteur’s demonstration of the contamination of environments by airborne germs contributed to the development of the concept of sterilization. In 1865, Joseph Lister (1827–1912), inspired by Pasteur’s results, developed the methods of antiseptics, which allowed him to eliminate germs by killing them with a disinfectant.

From the end of the 1860s, Pasteur devoted his work to contagious diseases. Between 1865 and 1870, he confirmed that the silkworm disease, pebrine, which was rampant in France, was correlated with the presence of particular corpuscles in the worm’s tissues. It will be shown that they were in fact spores of a sporozoan. Pasteur succeeded in eliminating the disease locally, by examining the crushed tissues of females with a microscope and by eliminating the eggs of those in which corpuscles were found.

After 1870, he conceived contagious diseases as being due to microbial germs that had entered

the organism. In this, he opposed certain authors, notably Prussian, such as Rudolph Virchow (1821–1902), who considered Pasteur’s position as vitalist and wanted to explain these diseases by physicochemical factors.

In 1877, Pasteur carried out cultures of the bacteria contained in the blood of sheep suffering from anthrax and showed that these were the agents. He recommended burning the carcasses of dead sheep to eliminate the germs.

Finally, during the last years of his life, he was particularly interested in vaccination and thus continued the work started by Edward Jenner in 1796. In 1880, he discovered that hens inoculated with ancient cultures of hen cholera germs suffered only a moderate illness from which they recovered when exposed to the germ again. And so, by attenuating germs by heating, he developed a vaccination process that protected sheep against anthrax. Pasteur’s work on rabies remains the most emblematic in this field. Knowing that the symptoms of this disease mobilize the nervous system, Pasteur used the brain of a trepanned dog as a culture medium and, from the substance of the spinal cord of a rabid animal, obtained the attenuation of the virus by letting the spinal cord dry out in the air. He succeeded in immunizing dogs and tried a first application on humans in July 1885.

On the strength of these successes, Pasteur created the Pasteur Institute, which was inaugurated in October 1888.

During his career, Pasteur tackled fundamental problems of biology in a very concrete way. Two of his main results have particularly marked the history of studies on the origins of life. The dissymmetry of the molecules of living organisms (chirality) that he demonstrated remains one of the characteristics of living organisms in which exobiologists are particularly interested. Moreover, his refutation of spontaneous generation also marked the biology of the end of the nineteenth century and has remained a reference for biologists.

Lowell, Percival

Kevin Schindler

Lowell Observatory, Flagstaff, AZ, USA

History

American astronomer Percival Lowell (1855–1916) established Lowell Observatory in 1894 primarily to study Mars and the possibility of life on that planet. He popularized the theory that intelligent life on Mars built a series of canals to direct water from the polar ice caps to the rest of the planet.

Percival Lowell earned his bachelor's degree in mathematics at Harvard University in 1876, studying under the eminent professor Benjamin Peirce (1809–1880). After splitting the next 17 years between overseeing the finances of his uncle's textile mills and traveling to the Far East, Lowell built his astronomical observatory in 1894 in Flagstaff, Arizona. His primary observing instrument was the 24-in. Clark Telescope, the sixth largest refracting telescope ever operated in the United States.

Lowell believed that the solar system developed through a process of planetary evolution that he later termed “planetology.” This theory suggested that Mars had reached a stage of development at which plant and, ultimately, animal life existed. This theory, coupled with the apparent network of waterways crisscrossing the planet that Lowell and other astronomers had observed through telescopes, served as proof to Lowell of intelligent life on Mars. Lowell never speculated about the exact nature of this Martian life except that it was intelligent. He did, however, admit that such Martian life would have adapted to the unique atmospheric conditions of Mars and thus likely appear much different than life on Earth.

Lowell published his observations and theories in various scientific publications. Some astronomers embraced Lowell's controversial ideas while others denounced them. In both cases, Lowell inspired further Martian studies from peers intending to either prove or disprove Lowell's pronouncements. Lowell also took his theories to

the public, popularizing the concept of intelligent Martian life by giving spellbinding public lectures and summarizing his ideas in books, newspapers, and magazines.

Lowell died in 1916, still believing in intelligent Martian life even though the mainstream scientific community had by then generally abandoned the idea. Still, some scientists continued to depict the alleged canals on maps up into the 1960s, when Mariner 4 and later spacecraft failed to detect the features.

In retrospect, Lowell profoundly impacted both scientific and literary thought, from the late nineteenth century into the twenty-first century and undoubtedly beyond. In astronomical circles, his compelling theories inspired comprehensive studies of the red planet, from Earth-based observations to up-close examinations by rovers, made possible by spacecraft landing on the Martian surface. Moreover, Lowell almost singlehandedly built a consciousness in the minds of the lay public that mysterious Mars may be home to intelligent life. Writers of fiction, such as H.G. Wells and Edgar Rice Burroughs, quite naturally picked up on this phenomena and incorporated Martian life scenarios into their works, significantly adding to the genre now recognized as science fiction.

Lucretius

Richard Hutchins

University of Miami, Miami, FL, USA

Keywords

Atomism · Astrobiology · Cosmology · Evolutions

Definition

Lucretius was a Roman philosopher, poet, and scientist. His poem, *De rerum natura*, or *On the Nature of Things*, is our fullest source of Epicureanism and ancient atomism. Lucretius presents ingenious arguments about the eternity of the universe, the infinity of space, the plurality of worlds, and the origin of life and humankind, the latter of which includes proto-evolutionary views about the origins of human thought, language, and society. His thinking had a major impact on early modern science.

Overview

Titus Lucretius Carus, and his epic poem *De rerum natura* (or *On the Nature of Things*), is our fullest source for Epicurean philosophy, science, and cosmology. It is also the only detailed account of ancient atomism to come down to us. Living over 2000 years ago, Lucretius was a poet, philosopher, and scientist. He wrote in Latin verses and synthesized the thoughts of the Greek philosopher Epicurus (341–270 BCE), who himself wrote in prose and was the founder of the Epicurean school of philosophy in Athens, two hundred years before Lucretius. About Lucretius himself, we know less than about any other major Latin poet. He lived in the waning days of the Roman Republic, from roughly 99–55 BCE. He was a contemporary of Cicero, who mentions the genius (*ingenium*) and artistry (*ars*) of Lucretius' poem (Cicero, *Cicero: Letters to Quintus and Brutus*, 2.10). It is possible that Lucretius lived

near the bay of Naples, but nothing certain is known of his birth, residence, or social status. The *gens Lucretia* was an aristocratic Roman family and Lucretius likely belonged to it (Don and Peta Fowler, xi–xiv).

The title of Lucretius' poem, *De rerum natura*, has been variously rendered into English. The most common translation is *On the Nature of Things*, but it might be better entitled *On the Nature of the Universe*, since it represents an attempt, in six “books” of roughly 1200 lines each, to explain the entire universe, from the motion of atoms to the origins of life and civilization to the existence of an infinite universe with multiple worlds. *De rerum natura* is a theory of everything. Unfortunately, Lucretius probably did not live to finish it. It is possible, however, that the gaps in the poem are the results of the historical vagaries of textual transmission, and not the failure of Lucretius to finish his *magnum opus*.

Book One of *De rerum natura* presents an outline of atomism and its philosophical rivals. Book Two delves more deeply into atomic motion and shows how atoms combine to produce the world we experience. Book Three uses the theory of atoms to argue that the soul is a physical thing, that it is not immortal, and that “we” no longer exist once the atoms of our soul and body have dispersed. On Lucretius' view, we have no need to fear death or what happens after death, since once our soul has dispersed, we experience no more sensation. Book Four discusses mental operations, acoustic and optical illusions, and ends with an aggressive critique of romantic love as just another harmful illusion. Book Five explains the creation of the world by atoms, the origins of animal life, the origins of human life and society, as well as the rise of civilization and its eventual collapse under empire. Book Six presents naturalistic explanations of potentially frightening meteorological and terrestrial phenomena that, in Lucretius' time, were used as evidence of divine intervention in the world, such as earthquakes, floods, lightning, and clouds. Lucretius shows that these phenomena can be fully accounted for by his theory of atoms, with no need to invoke gods. Book Six, the final book of *De rerum natura*, ends grimly, with humans trapped in a

plague-ridden Athens fighting over space on funeral pyres to cremate dead bodies.

There has long been debate about whether Lucretius meant to end *De rerum natura* on such a menacing note, or whether he intended to write a further, more serene, book about the lives of the gods as models of *ataraxia*, or “tranquility” – the ethical goal of Epicureanism (Giussani, xi–xxvi). The strongest evidence that Lucretius intended to write a further book about the gods comes from *De rerum natura* 5.155, where Lucretius promises to discuss the life of the gods as models of tranquility – a promise which he does not fulfill in the poem as we have it. Most scholars today believe that Lucretius meant to end *De rerum natura* with Book Six, and the plague (Cf. *De rerum natura* 6.92–5). A popular view sees the plague as a test of the reader’s ability to maintain *ataraxia*, or “tranquility,” in the face of the death and atrocity that Lucretius presents in his account of the great plague at Athens (Clay, 157–60). On this view, the goal of Lucretius’ extended discussions of atomism, cosmology, and natural causes throughout *De rerum natura* is to liberate the reader from the fear of death and from religious superstition.

Lucretius did not invent atomism. It was an inheritance from Leucippus (fifth century BCE) and Democritus (c. 460 – c. 370 BCE), both of whom were Greek Presocratic thinkers. Their atomism was later picked up and modified by Epicurus. Leucippus and Democritus were the first to argue that the ultimate constituents of the universe are maximally small bodies that cannot be seen with the naked eye. Lucretius believes, like Leucippus and Democritus, that atoms are infinite in number, but unlike Leucippus and Democritus, he does not believe that the atoms are infinite in shape. The fact that atoms have shape forces Lucretius to reckon with the problem of atomic minima, or “minimal parts” (*minimae partes*) as he calls them, of the atom. Lucretius describes a *minima pars* as the minimum of extension in an atom, essentially a point. Minimal parts, in Lucretius’ theory, are the smallest points in an atom, that when combined make up the shape of the atom, but that themselves cannot be separated from the atom (1.599–634). The word *atomos* (ἄτομος) comes from ancient Greek and means

“un-cuttable” (*a-tomos*). So, even though atoms, for Lucretius, have minimal parts, the atom as whole cannot be cut, because its minimal parts are too closely packed, and the atom is too solid and singular to be divided (Bailey 1947, 700–708).

The Greek atomists Leucippus and Democritus were not only atomist but also determinists. They believed that free will cannot exist in an atomic universe in which everything is reducible to physical cause and effect (Laks & Most, pp. 138–9 = D73). Epicurus took up Leucippus’ and Democritus’ atomism, but rejected their determinism (Long, 75). Epicurus simply asserted that there is free will, and late in his life seems to have hypothesized a physical “swerve” (*parenklisis*) of atoms to explain how free will is possible in an atomic universe. Epicurus, thus, seems to locate the possibility of free will in unpredictable swerves of atoms (Sextus Empiricus, *Against the Professors*, 11.96). Lucretius’ account of the swerve picks up from Epicurus, and is the only detailed surviving account of the swerve that we have. It can be found in Book Two of *De rerum natura* (2.216–24), where Lucretius says that originally, before any worlds existed, atoms were falling eternally through the void like rain, straight down, until one swerved “at an indefinite time” (*incerto tempore*, 2.218) and “in indefinite places” (*incertisque locis*, 2.219). After this swerve, atoms began to collide, hook together, and amass worlds.

The Epicurean theory of the swerve was mocked in antiquity (Usener, §281, 199–202). Recently, however, it has regained some respectability as a forerunner to the idea of indeterminacy in quantum physics. There has been much debate in scholarship about how often Lucretius thought swerves occur in the universe. One interpretation has it that swerves occur before every free action (Giussani, 135–41; Bailey 1928, 319–23). Another theory has it that swerves occur as little as once in a person’s lifetime. On this latter view, the swerve is a deviation in the person’s atomic makeup, or character, sufficient to allow that person’s subsequent actions to be free in the sense that, after the swerve has occurred, the ultimate source of that person’s actions cannot be traced to anything outside the person (Furley, 232). In

Lucretius' poetic phrase, "it bursts the bonds of fate" (*fati foedera rumpat*, 2.254). In her masterful overview of this issue, Elizabeth Asmis suggests that swerves happen at the beginning of each free act, but that they are the result of a "striving," or *voluntas*, on the part of the agent. Asmis also notes that when Lucretius describes the swerve in Book Two of *De rerum natura*, he uses the subjunctive mood. This suggests that the swerve was a hypothesis or theory rather than a committed doctrine among Epicureans (Asmis 1990, 275–91). As can be seen from the example of the swerve, Lucretius does not deviate substantially from Epicurus' atomic theory, and is often our fullest source for it. The principles of Lucretius' atomism are the following.

The universe – what Lucretius calls *natura* – is ultimately atoms and void. All other objects in the universe are compounds of atoms and void. Atoms, void, and the sum of the universe that atoms and void together make up, are the only indisputably everlasting things. Universes and worlds may form and collapse, but there will always be atoms moving in the void (5.351–62). Lucretius, therefore, does not believe in the creation of the universe as a whole, in the sense of something coming from nothing. Lucretius does, however, believe in the creation of individual worlds by the chance collision and compounding of atoms, with no gods guiding the process. In arguing for the eternity of the world, Lucretius seems to have applied something like "the principle of sufficient reason," often said to be the discovery of Spinoza or Leibniz in the seventeenth century (Cp. Melamed and Lin 2018).

Lucretius was not original in using the principle of sufficient reason to argue for the uncreated status of the world (for the "principle of indifference" in Epicureanism, cf. Taub 115–16; Asmis 1984, 265, 310–11, 319, 335). The Greek Presocratic philosophers Anaximander, Parmenides, and the atomists Leucippus and Democritus had already used the principle of sufficient reason to this end. In Lucretius' version of this argument against creationism, he says, "The first principle of our study we will derive from this fact: that nothing can come from nothing by divine power (*divinitus*)" (1.149–50). Lucretius goes on to

demand of the creationist that he or she give a sufficient reason as to why we should be persuaded that the universe came from nothing rather than from something already existing, and why creation happened at one specific time rather than another, or why we do not still observe things being created out of nothing now. Lucretius mocks *ex nihilo* creation as a view in which, if true, "men could arise from the sea, scaly tribes from the earth, and birds burst from the sky" (1.161–2). Lucretius' main line of attack is that the theory of *ex nihilo* creation, relying as it does on the impulsiveness of creator gods, cannot account for the regularity we observe in the world.

Only the concept of "seed," Lucretius thinks, can explain the regularity, or "reason" (*ratio*), of nature, that is, the idea that each atomic compound has a structure the reproduces itself with no need of outside or divine intervention: "For if things came out of nothing, all kind of things could be produced from all things, nothing would need seed" (1.159–60). Lucretius' argument that "nothing comes from nothing" (*nullam rem e nihilo gigni*, 1.150) implies both that the sum of atoms in the universe cannot be increased or decreased and that each thing in a world has "seeds" (*semina*) that guarantee the regularity of its growth, development, and ultimately the regularity of the world itself (Leonard and Smith, 220). Anthony Long has argued that by "seeds" of a world, Lucretius does not mean so much individual atoms as "atomic nuclei," that is, atomic compounds suitable for building a world that contains regularity (Long, 78).

Lucretius also seems to believe that the gods themselves are atomic compounds, and that they live in the spaces between worlds (*intermundia* in Latin; *μετακόσμια* in ancient Greek). The spaces between worlds make it less likely that the gods will be struck by stray objects moving through space. On this view, while the gods are by definition beings that do not die, they could in principle be destroyed if an atomic body were to hit them. Other Epicureans, however, thought that the gods were only ideal images, or thought constructs. The gods, on this view, are not physical and do nothing more than present an image of the life of *ataraxia*, or tranquility, to the human mind that humans

should strive for. Epicureans believe that humans in the state of nature naturally saw true images of the gods, images that were later corrupted by society and institutional religion (Cicero, *On the Nature of the Gods*, 1.49; Sextus Empiricus, *Against the Professors*, 9.43–7).

Lucretius also made famous an ingenious argument by the Greek Pythagorean philosopher Archytas about the infinity of space, against predecessors who believed that the universe as a whole has an outer limit (Taub, 112–13). Lucretius uses a thought experiment in which a person runs to the edge of the universe and throws a spear. Where would the spear go, Lucretius asks: “If all space (*omne quod est spatium*) is finite (*finitum*), suppose someone were to run to the outermost edge and cast a flying spear, would the spear, thrown with force, go where it was sent and fly far away, or do you think something would be able to hinder (*prohibere*) it and stand in its way (*obstare*)?” (1.968–73). From this, Lucretius believes that he has forced the reader to conclude that there can be no limit to the universe, and that the universe is infinite.

Because the atoms and the universe are infinite, Lucretius thinks that there must be infinite worlds. He follows Epicurus in this claim (Epicurus, *Letter to Herodotus*, §49; *Letter to Pythocles*, §89; in Gerson & Inwood). As Lucretius puts it: “If the same force of nature stands ready to throw the seeds of things together into a place in the same way as they have been thrown together here, then of necessity you must confess that other earths (*terrarum...orbis*) exist in other places (*aliis...partibus*), with varied tribes of men and generations of beasts” (2.1072–6). Consonant with his idea that the sum of atoms in the universe is constant, Lucretius also believes that the distribution of kinds of plants, animals, and humans on infinite worlds will be consistent across the universe. For instance, while one world may have more elephants than another or no elephants at all, the number of elephants in the entire universe, Lucretius believes, will be constant. Lucretius even considers the possibility of extinction on our world, but nonetheless believes that if an animal kind goes extinct on this world, there will be others on other worlds to maintain the balance

of animal kinds in the cosmos. This is the doctrine of *isonomia* (ἰσονομία), or “equality of distribution,” and Lucretius inherited it from Epicurus.

Worlds form when atoms happen to collide in space and hook onto each other. As this proceeds and a world takes in atoms from outside it, that world grows. Lucretius compares the growth, maturity, and decay of worlds to the life cycle of the human body, describing the increase of atoms in a world during its growth phase in terms of a human body increasing in power as it takes food into its veins (*venas*, 2.1119; 2.1125; 2.1148). At a certain point, however, a world reaches a tipping point and begins to lose more atoms into the void than it gains from it. Such a world grows old and dies, becoming gradually less fertile and producing ever smaller plants and animals. This dying world becomes increasingly harder for humans to cultivate and for animals to feed themselves on, until, finally, it collapses back into the void (2.1145.74). Lucretius’ idea that worlds are mortal is in stark contrast to Aristotle’s view that worlds are immortal and unchanging, and that animal kinds are fixed (Solmsen 1953, 50; Schijvers 2007, 272–3).

After describing the creation of our world by atoms at the beginning of Book Five, Lucretius turns to the origins of life and of the human race (5.772–1011). The first forms of life, Lucretius believes, were grasses and trees. Then birds and other animals sprang up by spontaneous generation: “formed by the rain and the warm heat of the sun” (5.798). Lucretius then tells us that these original creatures were nourished by wombs (*uteri*, 5.808) growing from roots in the earth, presumably to explain how the first animals, whom Lucretius imagines as “infants” (*infantum*, 5.810), were fed and protected until they broke out of the wombs of mother earth (*terra mater*, 5.796–7) to fend for themselves, in an explanation of the origins of life similar to the one described by the Greek Presocratic philosopher Anaximander. Lucretius then says that many of these first animals were born with the wrong mouths or genitals, and were therefore unable to feed or reproduce their kind. About these early “monsters and portents” (*monstra ac portenta*, 845), Lucretius says: “For we see that living beings need

many things in conjunction to be able to forge out the chain of generations by procreation: first there must be food, then there must be a way for the life-giving seeds (*genitalia...semina*) throughout the limbs and members of the body to flow out of the slackened body; and that male and female be able to join, they must have the means to exchange mutual pleasures” (5.849–54). Lucretius here explains how all the animal kinds that exist today are simply those “monsters and portents” who were able successfully to feed and reproduce themselves in the survival-of-the-fittest atmosphere of the youthful earth. As Gordon Campbell puts it: “We are all descendants of *portenta*, but of ones successful in competition” (Campbell, 115–6).

Lucretius then describes the origin of the human race (*humanum genus*, 5.925–1010). Because Lucretius does not believe that the world was divinely created, he thinks that it was neither purpose-built for human flourishing nor to be hostile to it. Like any other animal, humans exist today because we outlasted the struggle for life in the state of nature. Lucretius describes early humans as bigger than humans now, and more like animals. They lacked reason and language, and lived a semi-nomadic existence, passing their lives “in the wide-wandering fashion of wild beasts” (*volgivago vitam tractabant more ferarum*, 5.932). The early human mind, as Lucretius describes it, was a *tabula rasa*, devoid of any innate ideas. Humans gradually developed intelligence, Lucretius thinks, by learning from their environment. Through repeated interactions with things in the natural world, the early human mind was slowly populated with concepts, or “*prolepseis*” (προλήψεις), until humans began to have clear mental images of things and thereby develop rationality. Lucretius ends his description of early human life by recounting how they ultimately survived and escaped the state of nature by forging a social contract with one another for mutual protection. The protection afforded by the social contract allowed humans to settle down into communities and families, which in turn provided the social context for the emergence of language, which Lucretius describes as arising through social need (*utilitas*, 5.1029). And

language, as Lucretius tells the story, is only a short step away from the beginnings of civilization (5.1011–1090).

Lucretius’ *De rerum natura* represents a stunning attempt by a poet-scientist to account for the entire nature of the universe through the physical theory of atoms. The poem is rich with details of atomic, natural, meteorological, astronomical, and astrobiological phenomena, as well as imaginative thought experiments and logical proofs. While the majority of the poem focuses on detailed points about the working of the natural world and cosmology, its aim is ultimately ethical: to rid the human soul of fear of the gods and fear of death through the knowledge of nature and its causes. It is a work of liberation, in which the knowledge of nature is the ultimate source of freedom. As Lucretius put it: “If you know these things well, you will see at once that nature is free, free from proud masters – that nature by herself performs all things with her own resources without the aid of the gods” (2.1090–93).

Basic Methodology

The basic methodology of this entry is Classics and the History of Science. Lucretius is our fullest source of Epicureanism and atomism in classical antiquity.

Key Research Findings

Lucretius’ epic Latin nature poem not only anticipates many early modern discoveries in physics, biology, and cosmology, but is at heart a poem of liberation. Lucretius believes that understanding the causes of things in nature will eliminate fear of the gods, religion, and human mortality.

Future Directions

Scholarship on Lucretius has tended to focus on “source criticism,” that is, uncovering the earlier atomistic and Epicurean sources that Lucretius read before putting down his ideas in the epic

Latin nature poem *De rerum natura*. Future directions for the study of Lucretius might include comparing and connecting Lucretius' atomism, biology, and cosmology to later developments in these fields.

Luminosity

Daniel Rouan

LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

The luminosity of a celestial object is the total electromagnetic power it emits; this depends in most cases on the object's surface temperature and surface area. Symbol: L ; unit: W, or in terms of the Solar Luminosity (3.839×10^{26} W). The

luminosity can sometimes be defined for a restricted spectral domain: For x-rays, visible, infrared, radio, etc., one uses then the symbols L_X , L_{vis} , L_{IR} , L_{radio} , respectively.

Lutetia

Stefano Mottola
German Aerospace Center (DLR), Institute of
Planetary Research, Berlin, Germany

Definition

(21) Lutetia is a Main Belt asteroid discovered in 1852 by Hermann Goldschmidt from Paris, France, and named after the Latin name of the city. With an equivalent spherical diameter of about 100 km Lutetia is a comparatively large asteroid and could represent a surviving member of the population of original planetesimals that contributed to the formation of the inner planets. In 2010 Lutetia was visited by the Rosetta spacecraft on its tour to comet 67P Churyumov-

Gerasimenko. The close flyby enabled its bulk density to be determined to about 3.4 g cm^{-3} , among the highest densities of asteroids measured so far. The images returned by the spacecraft revealed a body that experienced a complex collisional evolution, with multiple local resurfacing events and a thick regolith layer.

Ly α

Synonyms

[Ly \$\alpha\$](#)

Definition

In the hydrogen atom, the Lyman series of lines is emitted or absorbed during transitions between an excited state and the fundamental (ground) state. Lyman alpha (noted $L\alpha$) is the first and the less energetic of these lines and connects the electronic levels $n = 2$ and $n = 1$, where n is the principal quantum number. Most of stellar matter is hydrogen; hence Lyman alpha is a very prominent line in stellar spectra. At a wavelength of 121.5 nm, Lyman alpha photons are in the VUV (vacuum ultraviolet) domain and play an important role in the dissociation of interstellar or cometary molecules.

History

These lines were discovered in 1906 by the American physicist Theodore Lyman.

Acronyms

Myr

Definition

Ma is a common scientific abbreviation for Megayears = one million (10^6) years derived from the Latin *Mega-annum*. Note that the Latin accusative, *annum*, expresses an absolute age (e.g., the Earth is 4560 Ma old), while the English accusative, *years*, expresses a period of time (e.g., the Archean eon lasted for 1500 Myr). Ma is the most common unit of time used to describe events through most of the history of the Earth, the other planets, and meteorites.

Macro Monte Carlo Models

Eric Herbst
University of Virginia, Charlottesville, VA, USA

Definition

Rate equation models for the simulation of the chemistry occurring in interstellar clouds or extended stellar atmospheres are perfectly adequate for gas-phase chemistry but have several failings for the chemistry that occurs on and in

core-mantle dust particles. The major problem arises because dust particles are discrete entities, and reactions between species on one granular particle and another must be ruled out. If one considers grains separately, the often small number of important reactive species per grain is not treated well by rate equations, which are only useful for large concentrations of reactant species. One solution to this problem is the use of the master equation model in which rate equations are replaced with differential equations with time derivatives of the probabilities of finding selected numbers of species on a grain, and the coupled differential equations are integrated. Another approach to the problem, which has been utilized more extensively in the astrochemical literature, is the Monte Carlo method, which can be run for both macroscopic and microscopic models. The exact positions of each species are not calculated in the macroscopic method, which should yield the same probabilities as the master equation technique (Stantcheva et al. 2002). In both Monte Carlo approaches, solution of differential equations is replaced by the calling of pseudorandom numbers. In the macroscopic method, the chemical species are contained in a given region, such as the surface of an interstellar grain, or the gas in a bubble containing an interstellar grain. One starts with given concentrations for each species. The first event – a chemical reaction or a physical event such as the adsorption of a gas-phase species – can be obtained from a Markovian exponential distribution of time involving the sum of all processes between collisions and other events that change the concentrations. This is done by suitable choice of a pseudorandom number to determine the specific time at which the average sum of events occurs and another random number to determine what the event is, be it a desorption, an accretion, or a specific reaction. The relative probability of each event can occupy a range in the random number space between 0 and 1, with the range related to the probability of the event. The probabilities are obtained using the same rate expressions used

in the rate equation approach. After the necessary concentrations are updated, the time of the next average sum of events and a particular event is found. Eventually a whole Markovian chain of abundances at given times is obtained up to the maximum time desired. It must be noted that this chain represents just one evolution of the system, so that many more such chains must be investigated using a different random number to start the procedure. The macroscopic approach can be used for both gas-phase and grain-surface chemistry and can even couple the two together. Once a Monte Carlo approach is utilized for the granular chemistry, it must also be used for the gas-phase chemistry, because rate equations follow a very different clock. Recently, Monte Carlo models that are partially microscopic in nature have been developed (Vasyunin and Herbst 2013).

Macronutrient

Ricardo Amils

Departamento de Biología Molecular,
Universidad Autónoma de Madrid, Madrid, Spain

Synonyms

[Culture media](#); [Nutrients](#)

Definition

Macronutrients are nutrients required in large amounts for cell growth. All cells require carbon. On a dry basis, a typical cell is about 50% carbon, and this element is the major element in all classes of macromolecules. Some organisms are autotrophs and use CO_2 as the source of carbon. The rest are heterotrophs and they use reduced organic compounds as a carbon source. Heterotrophs require autotrophs for their carbon source. The next abundant element is nitrogen. A typical nitrogen content in a prokaryotic cell is about 12%. Nitrogen is found mainly in ► [proteins](#) and ► [nucleic acids](#). Nitrogen is available in both organic or inorganic forms. However, the bulk of available nitrogen is in inorganic form, either as ammonia (NH_4), nitrate (NO_3^-), or diatomic nitrogen (N_2). Most organisms can use ammonia or nitrate as a nitrogen source but only a few are able to fix atmospheric N_2 because of the strong triple bond. Other macronutrients are phosphorus, sulfur, potassium, magnesium, calcium, sodium, and ► [iron](#). Phosphorus occurs in nature in the form of organic and inorganic phosphate and is required by the cell primarily for synthesis of nucleic acids and phospholipids. Sulfur is needed for the synthesis of two aminoacids, cysteine and methionine, and is also present in vitamins and coenzyme A, an important biosynthetic cofactor. Most cellular sulfur originates from reduced (S^{2-}) or oxidized sources (SO_4^{2-}). All organisms require potassium. Different enzymatic activities require this cation specifically. Magnesium

stabilizes different cellular structures such as membranes, ribosomes, and nucleic acids. Calcium, which is not essential for cell growth, helps to stabilize cell walls, and is also fundamental for endospore heat stability. Sodium requirements are related to the ionic strength of the environment in which the organisms grow. Iron plays a fundamental role in important cellular functions including respiration.

Mafic and Felsic

Daniele L. Pinti

Geotop, Research centre for the dynamics of the Earth system, Université du Québec à Montréal, QC, Canada

Synonyms

[Basic and acid](#)

Definition

An igneous rock is mafic when its SiO₂ content is low, typically 50%, and felsic when this content is high, typically above 60%. The adjective mafic refers to a silicate mineral or rock (magmatic, either intrusive or extrusive) enriched in compatible elements (i.e., easily incorporated into a crystal structure and refractory) magnesium and iron (old term, *basic*). Typical mafic igneous rocks such as ► [basalts](#) contain ferromagnesium minerals such as olivine and pyroxene, and calcium-rich-plagioclase. Upon crystallization of the residual magma, the residual magmatic rocks concentrate incompatible elements (i.e., not compatible with a crystal structure, or fusible) such as silicon, aluminum, potassium, and sodium. Typical felsic (old term, *acid*) rocks such as [granite](#) contain quartz, potassium feldspar, and sodium-rich plagioclase.

Magma

Nicholas Arndt

ISTerre, University Grenoble Alpes, Grenoble, France

Definition

Magma is the molten or partially molten rock from which ► [igneous rocks](#) are derived through crystallization. It forms through melting of parts of the ► [mantle](#) (partial melting) or of the crust, either oceanic or continental (process of *anatexis*). On eruption, it forms volcanic rocks; when it solidifies in the crust, it produces intrusive or plutonic rocks. Its composition ranges from ultramafic (► [komatiite](#)) through mafic (► [basalt](#)) to felsic (► [granite](#)) and rarely to carbonatitic (carbonatite). Its temperature ranges from ca. 1600 °C in erupted komatiite to less than 700 °C in water-rich intrusive granitic magma. The viscosity ranges from about 1 Pa s (pascal-second) in carbonatite (that of water) through 10–100 Pa s in basalt (roughly equivalent to the viscosity of motor oil) to 10⁹ in rhyolitic magmas.

Magma Oceans

Sabrina Schwinger and Nicola Tosi
German Aerospace Center (DLR) Institute for
Planetary Research, Berlin, Germany

Keywords

Terrestrial planets · Magma · Planetary
interiors · Planetary differentiation · Giant
impacts

Synonyms

[Magma sphere](#)

Definition

A magma ocean is a layer of molten rocks of approximately uniform depth that behaves rheologically as a liquid, is globally distributed, and makes up a substantial volume fraction of a planetary body (e.g., Taylor and Norman 1992; Tonks and Melosh 1993). Smaller, more localized magma bodies may also be referred to as magma ponds. Magma ocean formation and its subsequent solidification are crucial mechanisms for the differentiation of terrestrial bodies into a metallic core, a rocky mantle and a rocky crust. Hence they play a fundamental role in shaping the evolution of rocky bodies.

Magma oceans are sometimes also referred to as magmaspheres. The term magma “ocean” is intended to describe the extent and the liquid-like rheological behavior of a magma volume, which, like all magmas, is generally a mixture of liquid, solid and gaseous phases. The term magmasphere is intended to avoid the term

magma “ocean,” which in analogy to water oceans, might be misinterpreted as describing a body that is completely liquid.

History

The term “magma ocean” has been established in the context of the early evolution of the Moon. Shortly after the identification of globally distributed anorthosite on the lunar surface in the early 1970s, the flotation of light plagioclase crystals in a global magma ocean was recognized as the most plausible mechanism to explain this peculiar characteristic of the surface of the Moon (e.g., Wood et al. 1970; Smith et al. 1970). Magma ocean formation was generally considered even more likely on planetary bodies larger than the Moon. Slower cooling associated with a lower area/mass ratio, the potential presence of an insulating atmosphere, a stronger heating by accretionary impacts, and the release of gravitational heat during core formation all concur to facilitate heating and melting of silicate rocks so that magma oceans were proposed also for the terrestrial planets (e.g., Warren 1985). In later studies, the term “magma ocean” was also adopted to describe global melting on asteroids (e.g., Righter and Drake 1997).

Overview

Formation of Magma Oceans

During the early stages of the evolution of planets, multiple energy sources concur to raise the temperature of silicates above their liquidus, leading to the formation of magma oceans (Warren 1985; Elkins-Tanton 2012; Solomatov 2015). Heat sources include radiogenic heating, accretion heating, impact heating following giant collisions, and gravitational heating due to metal-silicate separation upon core formation. The availability of these heat sources depends on the size of a planetary body and its actual formation time.

On the one hand, early formed small planetesimals (e.g., the parent bodies of differentiated meteorites) contained a sufficient amount of the

short-lived radioactive isotopes ^{26}Al and ^{60}Fe (with half-lives of ~ 0.7 and 2.6 Myr, respectively) to provide heat for their complete melting (e.g., Urey 1955). On the other hand, the terrestrial planets and parent bodies of undifferentiated meteorites formed at a later stage, when the short-lived radioactive isotopes had already decayed.

The heat produced by impacts depends on the size of the planetary body since the energy of the collisions increases with the size of the colliding bodies and larger bodies tend to cool more slowly (e.g., Tonks and Melosh 1993). For planet-sized rocky bodies, giant impacts, such as the one that may have led to the formation of the Moon (e.g., Barr 2016), are the dominant heat source for the formation of magma oceans. All rocky planets likely experienced giant collisions at some stage of their evolution that led to the formation of magma oceans (Quintana et al. 2016).

Although difficult to constrain due to the multi-stage nature of the process, the release of gravitational potential energy upon formation of the iron-rich core can also contribute decisively to large-scale silicate melting, in particular of the lower parts of the mantle (e.g., Rubie et al. 2015).

In the context of exoplanets, bodies orbiting close around their host star may also experience sufficiently intense radiative heating (e.g., Demory et al. 2016) or, because of high orbital eccentricities, tidal heating (e.g., Driscoll and Barnes 2015) to produce magma oceans.

Evidence for Magma Oceans

The Moon is the body for which the magma ocean phase is best documented. As revealed by samples and remote-sensing measurements, the ancient lunar highlands largely consist of anorthosites, mostly composed of plagioclase feldspar, which build a 30–40 km thick crust (Wieczorek et al. 2013). In a cooling magma ocean, plagioclase minerals form at conditions for which the crystals are lighter than the residual liquid. They tend to float to the top of the magma ocean forming the anorthositic crust. Such differentiation processes during magma ocean solidification explain the observed negative Eu-anomaly in the mantle

sources of mare basalts (by separation of Eu-enriched plagioclase from the rest melt) and the strong enrichment of crustal rocks in the Procellarum KREEP terrane in incompatible trace elements, that accumulated in the rest melt during the latest stages of magma ocean solidification (see Shearer et al. 2006).

For the terrestrial planets, an early magma ocean stage has been proposed as a likely explanation for their differentiated structure. Spectral measurements suggest that the dark character of Mercury's surface is due to graphite (Peplowski et al. 2016). Similar to anorthosites on the Moon, graphite is thought to have formed a flotation crust in a crystallizing magma ocean (Vander Kaaden and McCubbin 2015). The Earth's surface does not present direct evidence for an early magma ocean because of its continuous recycling due to plate tectonics. However, simulations of the Moon-forming impact indicate that the mantle of the proto-Earth underwent nearly total melting (e.g., Nakajima and Stevenson 2015). In addition, the budget of siderophile elements of the mantle is thought to be set by metal-silicate equilibration at the base of a deep magma ocean (e.g., Walter et al. 2000). Isotopic measurements of Martian meteorites suggest that the planet differentiated into mantle and core within the first few million years of the Solar System and that the mantle differentiated into distinct source reservoirs within a few tens million years of the Solar System (e.g., Elkins-Tanton 2012). Both findings contain strong indications that also Mars underwent an early magma ocean phase.

For early formed planetesimals like the asteroid Vesta, a magma ocean phase is inferred from the occurrence of differentiated meteorites originating from the asteroid belt (e.g., Neumann et al. 2014).

Properties and Evolution of Magma Oceans

Due to large uncertainties in current accretion models, the initial thermal state of planets and the extent of their magma oceans are not well known. The siderophile element content of the mantle provides some constraints on the depth of core-mantle equilibration, which have been used

to infer possible depths of magma oceans on Earth and Mars (e.g., Elkins-Tanton 2012). The depth of the lunar magma ocean is further constrained by the thickness of its primordial crust, the crystallization depth of crust-forming plagioclase, and the source depth of lunar volcanic glasses (Longhi 2006).

The duration of the magma ocean phase depends strongly on the presence or absence of insulating crusts or atmospheres. On the Moon, the formation of an insulating anorthositic crust on the surface of the magma ocean may have prolonged its solidification to up to 200 Ma (Maurice et al. 2020). In absence of an atmosphere, on planets like Venus, the Earth, and Mars, a magma ocean radiating heat to space is expected to solidify within a few thousand years (e.g., Lebrun et al. 2013). However, the large amount of greenhouse gases that are likely released upon magma ocean solidification can lead to the formation of a thick insulating atmosphere that can prolong the magma ocean lifetime to a few million years for a planet at Earth's orbit, or even to ~100 million years for a planet at Venus' orbit receiving a higher stellar radiation (e.g., Hamano et al. 2013).

Magnetic Anomaly

Nicholas Arndt

ISterre, University Grenoble Alpes, Grenoble, France

Definition

A *magnetic anomaly* is the local departure in orientation or strength from the large-scale pattern of a planetary magnetic field. Stripes of alternating positive and negative polarity parallel to isochrons in the Earth's oceanic crust record reversals of the magnetic field; they provided the first evidence of seafloor spreading. The pattern of variation of field direction and intensity is recorded in volcanic or stratigraphic sequences and provides the basis of the magneto stratigraphy. More localized anomalies provide information about the subsurface structure and composition of the Earth's crust and are an important index for the presence of certain metallic (generally ferruginous) ore deposits.

Definition

A magnetic field is a physical field that arises from an electric charge in motion, producing a force on another moving electric charge. Magnetic fields play a major role in star and planet formation, as well as at most stages of planetary system evolution.

Overview

Magnetic fields are present everywhere in the Universe, with intensities ranging from a fraction of a micro-Gauss (10^{-6} Gauss) in the intergalactic medium, to about 1 Gauss for the Earth magnetic field, and up to several peta-Gauss (10^{15} Gauss) in some highly magnetized compact objects, such as

neutron stars. They play an important role in most physical processes at work in the Universe, and are believed to be responsible for some spectacular behaviors, such as energetic collimated jets escaping from galactic nuclei or from protostars and young stars. They also constitute an essential ingredient of star and planet formation and their subsequent evolution. The Earth magnetic field has played and continues to play a major role in protecting our planet from impinging hard solar radiation, and therefore has had a crucial impact on the emergence and evolution of life.

Basic Methodology

Stellar magnetic fields can be measured thanks to the Zeeman effect on spectral lines: in presence of a magnetic field, spectral lines are split into multiple, closely spaced components, the so-called π and σ Zeeman components. There exist several ways of exploiting this property, the most efficient being the analysis of the light polarization induced by the Zeeman effect. Each one of the Zeeman components indeed is polarized in a particular way, linearly for the π components or linearly and circularly for the σ components. Circular polarization is sensitive to the line-of-sight (longitudinal) component of the magnetic field, while linear polarization is sensitive to the component of the magnetic field perpendicular to the line-of-sight (transverse). The strength and orientation of the star's magnetic field can thus be determined by a careful examination of the Zeeman polarization of spectral lines.

The instrument used for this purpose is called a spectropolarimeter, and consists of a high-resolution spectrograph combined with a polarimeter. Very powerful such instruments were developed in the last two decades, in particular ESPaDOnS on the 3.6 m Canada-France-Hawaii telescope (CFHT) on Mauna Kea, HARSPol on the 3.6 m telescope at ESO-La Silla, and NARVAL/NeoNARVAL on the 2 m Bernard Lyot telescope (TBL) at Pic du Midi in the French Pyrénées. The remarkable efficiency of these instruments allowed astronomers to measure

Magnetic Field, Fig. 1 The principle of Zeeman-Doppler imaging. In the upper row of the figure, a magnetic region is depicted at three different phases of the rotation,

while its corresponding circular polarization signature is shown in the lower row. Credit O. Kochukhov.

the magnetic fields of hundreds of stars of all types, providing valuable information on stellar magnetism. More recently, as described in section “[Future Directions](#)” below, an extension of spectropolarimetric techniques toward the infrared was developed, providing for instance the possibility to study magnetic fields in very cool stars.

The Zeeman polarization measurement described above provides the longitudinal or transverse component of the magnetic field (depending on the type of polarization, linear or circular, which is measured), averaged on all the visible hemisphere of the star at the moment of the observation. In order to reconstruct the magnetic field vector at all locations at the stellar surface, astronomers have developed the so-called Zeeman-Doppler imaging technique, which consists of monitoring the star during its rotation. A magnetic region appearing at the limb on the side of the star which is approaching the observer will produce a polarimetric signature at the blue edge of a spectral line, due to the Doppler effect. As the star rotates, the magnetic region will continue to approach the observer but with a decreasing velocity, and therefore its signature will move toward the center of the line. At some point, the meridian plane of the magnetic region will cross

the line of sight and the polarimetric signature will have a zero velocity in the observer’s direction, then it will start moving toward the red wing of the line, until eventually the magnetic region disappears at the opposite limb. The excursion of the polarimetric signal across the line and the speed at which it evolves from blue to red depend on the latitude of the magnetic region and on the inclination of the star’s rotation axis with respect to the line of sight.

Based on this principle, astronomers have developed powerful tools to reconstruct the topology and intensity of the magnetic field at the surface of a star, although it cannot be resolved directly.

Key Research Findings

Importance of Magnetic Fields for Planet Formation, Evolution, and their Habitability

Magnetic fields are believed to play a crucial role in the formation and evolution of stars and planetary systems. Stars are formed from molecular clouds in the interstellar medium, which are threaded by magnetic fields. The gas and the magnetic field are intimately coupled during star

Magnetic Field,

M

formation, the collapsing gas dragging in the magnetic field lines, while the magnetic field tends to slow down the collapse. This has a significant impact on the distribution of matter which is left behind in the nebula after the collapse, out of which planets form.

Magnetic fields are also an essential ingredient of the coupling between protostars or young pre-main sequence stars with their surrounding accretion discs. In these early phases of stellar evolution, this coupling is responsible for the transfer of angular momentum from the star to

the disc, and prevents the contracting star from spinning up to breakup velocity. It can be concluded that stars could not be formed in the absence of magnetic fields, hence that magnetic fields are crucial for the emergence of life, which definitely requires the energy provided by stars.

Moreover, stellar magnetic fields are coupled to stellar rotation throughout the evolution of a star. For solar-type stars, they are generated by dynamo action inside the star, whose efficiency is a strong function of rotation. Additionally,

Magnetic Field, Fig. 4 Dynamo generation of magnetic field in the Sun. Credit M. Dikpati

stellar magnetic fields, through their coupling with the stellar wind, enhance and control the angular momentum loss during the star's evolution. As a result, due to its magnetic field, a star will keep spinning down during its entire life, with a related decrease of its level of activity. Because the level of stellar activity and its accompanying particle bombardment can have a major impact on the appearance and evolution of life on a planet, stellar magnetic fields can definitely not be

ignored in this process. This relationship between stellar activity and life on a planet is further impacted by the eventual presence of a magnetic field on the planet itself, which can act as a shield against stellar particle bombardment.

Magnetic fields, both stellar and planetary, therefore play an essential role in stellar and planetary evolution, participate to the control of planet habitability, and may significantly impact the appearance and evolution of life on a planet.

Solar and Stellar Magnetic Fields

The first stellar magnetic field, that of the Sun, was discovered in 1908 by George Hale, who measured the field inside solar dark spots using the Zeeman effect on spectral lines. Since then, our understanding of the solar magnetic field has considerably progressed. The solar magnetic field can be approximated at first order by a dipole, and controls most of the active phenomena that it displays: solar spots, chromospheric plagues, filaments, corona, wind, flares, etc. However, the dynamo mechanism by which the solar magnetic field is generated and sustained is far from being fully understood.

Understanding the solar magnetic field is one of the motivations for studying the magnetic field of other stars, offering a wide range of physical conditions (rotation, convection, temperature, etc.), and which can therefore be used as cosmic laboratories to study stellar magnetism. It is also very important to understand stellar magnetic

fields because of their strong impact on stellar formation and evolution, as described earlier.

The Magnetism of Cool Stars

Magnetic fields of cool stars, such as the Sun, are believed to be produced within the convective zone, as the result of convection coupled with rotation. Differential rotation inside the star wraps and amplifies the magnetic field around the star, changing the seed poloidal field into an intense toroidal one. Convection and meridional circulation then regenerate the poloidal field from the toroidal one. Although the details of this mechanism still need to be worked out, it seems well established that this type of dynamo, which is responsible for the magnetic field of most cool stars, including the Sun, is predominantly located at the base of the convection zone, near its interface with the underlying radiative zone, where the differential rotation is maximum.

However, spectropolarimetric observations of various classes of cool stars, with various rotation rates and depths of the convective envelopes, have revealed the existence of several regimes of dynamo generation of magnetic fields. In particular, red dwarfs, which are entirely convective, and hence do not have any radiative-convective interface where dynamo action is supposed to be most effective, still exhibit intense, predominantly dipolar magnetic fields, in contradiction with predictions of the above simplified model. Stellar magnetism therefore still preserves some of its mysteries.

As a consequence of the dynamo regeneration of magnetic fields in cool stars, the major magnetic component reverses direction periodically. The cadence of these reversals is of the order of once every 11 years for the Sun, but can be considerably shorter or longer for other stars, depending on various parameters, in particular the amount of differential rotation.

The Magnetism of Massive Stars

In addition to cool stars with masses similar to that of the Sun, about 10% of the massive stars (more than twice the mass of the Sun) also exhibit intense, well-ordered, dipolar magnetic fields. These fields are believed to be fossil in origin, remnants of the weak magnetic field present in the molecular cloud out of which the star was formed. During the contraction of the star toward the main sequence, the magnetic field lines are frozen in the contracting plasma, and are therefore pinched, resulting in a gradual enhancement of the magnetic field intensity and the evolution of its topology toward a dipole.

The magnetic fields of these massive stars are thought to be responsible for a variety of properties, such as the presence of patches of chemical abundance anomalies seen at the surface of some of them.

The Magnetic Field of the Earth

Like the solar magnetic field, the magnetic field of the Earth is approximately a dipole, more or less similar to that of a bar magnet. The Earth magnetic axis is tilted by about 11 degrees with respect to its rotation axis. The magnetic poles are therefore

near (but not at) the geographic poles. The magnetic field is generated and sustained in the liquid outer core by a dynamo process involving convection of molten iron and rotation. The strength of the field at the surface of the Earth is approximately 0.5 gauss in average, but varies over the surface in the range 0.3 Gauss (in the area including South America and South Africa) to 0.6 Gauss (around the magnetic poles in northern Canada and southern Australia, and in Siberia).

The direction of the Earth magnetic axis is not constant in time. The geographic location of the magnetic poles has considerably varied over the centuries. Rock specimens of different ages found at the same location have different directions of permanent magnetization, indicating this long-term variation of the Earth magnetic field orientation. Evidence is found for 171 magnetic field reversals during the past 71 million years. The locations of the magnetic poles move as much as 15 km every year.

The magnetic field extends to thousands of kilometers above the Earth into a gigantic magnetosphere which shields us against solar high energy charged particles, which otherwise would have prevented life on Earth. The Earth's magnetosphere deflects most of the solar particles. Some of them are trapped in the so-called Van Allen radiation belt. Frequently, the Earth's magnetosphere is hit by energetic solar flares causing geomagnetic storms, giving rise to boreal and austral aurorae. During these events, a small number of solar charged particles reach the Earth's upper atmosphere and ionosphere in the polar zones, channeled along the magnetic field lines.

Star-Planet Interactions: The Role of Magnetic Fields

Special attention is being paid presently to the interaction of close-in Jupiter-sized exoplanets with their host stars. Evidence has been accumulated in recent years that large size planets orbiting very close to their star can have a significant influence, through tidal effects, on the activity behavior of their star. If the planet is itself magnetic and orbits a magnetic star, we can expect a complex interaction between the planet magnetosphere and that of the star, comparable to some extent to the

well-known Io-Jupiter system interaction. It has been recently conjectured that the magnetic interaction between close-in giant planets and their host star could play a dominant role in the migration and evolution of these planets.

One example of this kind of star-planet magnetic interaction is provided by the τ Bootis system, in which a $4.4 M_{\text{Jup}}$ planet orbits a solar-type star at the distance of 0.049 AU. The star τ Bootis has been shown to be magnetic, with a magnetic field intensity of the order of a few gauss, and to have a strong surface differential rotation. The planet orbital motion is synchronized with the star's rotation at intermediate latitudes. The magnetic field reverses its polarity approximately every 2 years, that is, much more often than the Sun. The potential magnetic interaction between this star and its planet has triggered a major interest in recent years.

Future Directions

Most of the results obtained so far in the field of stellar spectropolarimetry, and briefly summarized in the previous chapters, were obtained in visible light. The foreseen future of this field consists mostly in an extension of this technique to the infrared and ultraviolet domains.

These developments are already well underway toward the infrared with instruments such as the SPIRou spectropolarimeter installed at CFHT, soon to be complemented by a twin instrument (SPIP) at TBL. Extending spectropolarimetric techniques toward the infrared provides an easier access to the measurement of magnetic fields in stars cooler than the sun, such as M dwarfs and brown dwarfs, as well as access to objects in heavily obscured environments, such as protostars, and to magnetospheres around hot stars.

In parallel, projects for the development of spectropolarimeters in the ultraviolet are currently under study, with the additional difficulty of the need to go to space because ultraviolet radiation is blocked by the earth atmosphere. Several space mission projects for ultraviolet spectropolarimetry exist, ranging from nanosatellites, such as the

CASSTOR project under study in France, to medium size missions, like the Polstar satellite proposed to NASA or the Arago project proposed to ESA, or large size missions such as LUVOIR (Large UV/Optical/Infrared Surveyor), an 8 m space telescope recently recommended by the US Astronomy decadal survey, for which a UV spectropolarimetric instrument (Pollux) is planned. Spectropolarimetry in the ultraviolet will open a new discovery space, from the environment of magnetic hot stars to the interactions between cool stars and their planets.

Core · Dipole field · Dynamo · Induced magnetic field · Magnetometer · Remnant magnetic field

Definition

The magnetic field of a ► [planet](#) or satellite can be measured by magnetometers onboard orbiting space craft or – more locally – onboard landers and rovers. The magnetic field at any given point has a strength and a direction and thus is a vector field. On a global scale and measured at some distance from the planet or satellite, planetary magnetic fields resemble dipole fields. On or close to the surface the field is typically of more complicated topology. Planetary magnetic fields are generated by a ► [dynamo](#) mechanism in the iron-rich liquid core shells of ► [terrestrial planets](#) and satellites, in metallic ► [hydrogen](#) shells in ► [Jupiter](#) and ► [Saturn](#), and in ionic oceans in ► [Uranus](#) and ► [Neptune](#). Magnetic fields may be also induced in electrically conducting oceans in icy moons such as the Jovian moon ► [Europa](#). Local magnetic fields may be caused by remnantly magnetized ► [rock](#).

Overview

Magnetic fields are – in general – detected by the force they exert on magnetic materials and electrical charges. This principle is used in magnetometers onboard spacecraft with which magnetic fields around planets are detected and measured. The magnetic field strength is a vector quantity and is measured in the SI unit tesla [T]. In geophysics and planetary physics, the *cgs* units Gauss [G] and gamma [γ] are still widely used with 1 γ equaling 10^{-3} G and 1 G equaling 10^{-4} T. The terrestrial planets ► [Earth](#) and ► [Mercury](#) are known to have global magnetic fields. The Earth’s field is known to vary in time, with short period and secular changes and polar wander (motion of

the North and South Poles with respect to the solid ► [crust](#)). The polarity of the field has changed over geological history on time scales of 10^5 a. The Earth’s magnetic field strength varies between 25,000 and 65,000 nT with the maxima near the poles and the minimum near the equator.

The magnetometer onboard the ► [Mars Global Surveyor](#) Mission discovered local magnetic fields on ► [Mars](#), mostly in the southern hemisphere, that have been interpreted to be due to magnetized crustal rock provinces with varying strength and direction of magnetization. This observation indicates that Mars once had a global magnetic field, the polarity of which may have varied in time similar to the Earth’s field. Magnetized crustal rock units have also been discovered on the Moon.

The planets of the outer Solar System Jupiter, Saturn, Uranus, and Neptune all have global magnetic fields. Periodically varying magnetic fields have been discovered around ► [Europa](#), ► [Ganymede](#), and ► [Callisto](#), the icy satellites of Jupiter. These fields vary in time with the orbital periods of the satellites, which are on the order of days. In addition, Ganymede has a steady global magnetic field. This satellite is the only satellite known to posses such a field.

Global magnetic fields of planets largely resemble dipole fields (the field of an ideal bar magnet). A simple representation of the global magnetic field is the offset tilted dipole. This dipole is characterized by a moment (a vector quantity) $\vec{M}$ and an offset vector $\vec{r_0}$ measured from the figure center of the planet. The dipole moment is measured in Tm^{-3} , and the tilt is measured relative to the rotation axis. Table 1 collects dipole moments and tilts for the planets with known global magnetic fields. More detailed representations of global magnetic fields use spherical harmonic functions.

Magnetic Field, Planetary, Table 1 Dipole moment and tilt of planets and satellites with known active magnetic fields

	Mercury	Earth	Jupiter	Ganymede	Saturn	Uranus	Neptune
Dipole moment [$10^4 \text{nT} \cdot \text{R}^3_{\text{p}}$]	0.019	2.58	42.8	0.07219	2.11	2.28	1.42
Tilt [°]	4.5	11	9.5	176	1	60	47

The offset in terms of the planetary radius is usually small, suggesting that the magnetic field is generated deep in the interior. Exceptions are Jupiter with $0.11 R_p$ and even more so Uranus and Neptune with 0.33 and $0.55 R_p$, respectively (e.g., Connerney 2015). It is held that in these planets the dynamo is closer to the surface.

A planet with an intrinsic magnetic field stands as an obstacle to the solar wind with an interaction region that resembles a set of nested conic sections (Fig. 1). The outer section is called the bow shock. It marks the shock-wave front that is created by the impingement of the supersonic solar wind on the planetary field. The slowed solar wind mostly flows around the obstacle within a region called the magnetosheath. The latter is bounded on the one side by the bow shock and on the other by the magnetopause. Within the magnetopause is a region called the ► [magnetosphere](#) that is mostly filled by the planetary field. The magnetosphere extends downstream into the magnetotail.

In terrestrial planets and in Ganymede, the global field is agreed to be produced in their fluid iron cores or core shells by a ► [dynamo](#). In the ► [giant planets](#) Jupiter and Saturn, the field is generated by dynamo action in their metallic hydrogen shells. In Uranus and Neptune, the field is held to be produced in ionic oceans.

Magnetic Field, Planetary, Fig. 1 Solar wind interaction with the terrestrial magnetic field. (Adapted from Baumjohann and Nakamura 2015)

Rock that contains sufficient amounts of ferri- and ferromagnetic materials can be magnetized in a planetary magnetic field. Part of the magnetization can be permanent or remnant at temperatures below the Curie temperature. The value of the Curie temperature varies between ► [minerals](#) but is typically between 500 and 1000 K. The remnant and the induced magnetizations are vector quantities. The direction of the remnant magnetization reflects the direction of the magnetizing field at the time of the cooling below the Curie temperature. Therefore, remnant magnetization data can be used to reconstruct the evolution of the global magnetic field and the movement of crustal units relative to, for example, the poles of the magnetic field. Remnantly magnetized crustal units are known from the Earth, Mars, and the Moon. For the Earth, remnant magnetizations have been used to date the spreading of the oceans and to determine its rates, continental drift, and polar wander as well as the evolution of the magnetic field and its polarity. For Mars, the magnetization patterns have been interpreted as indicating a global magnetic field in the first 500–1000 Ma that may have experienced polarity reversals. This field would have been similar in strength to the present global field of the Earth. For the Moon, an early field has been suggested, but it has also been proposed that the magnetizing field may have been due to plasma that emanated from large impacts (Hood and Vickery 1984).

The periodically varying fields of the icy moons of Jupiter have been interpreted as induced fields (Kivelson et al. 1999). If the satellites contain an electrically conducting layer of sufficient conductivity then their moving through the magnetic field of Jupiter along their orbits will induce a time-varying current. That current by the laws of induction will induce a magnetic field. Salty ► [water](#) will have a sufficiently strong conductivity. The geometry of the field also suggests that the conductor cannot lie deep in the satellite. The induced fields thus have been taken to suggest the existence of (ice-covered) oceans.

The presently available data for Mercury interpreted together suggest a dipole tilted by

5° with a moment of $190 \text{ nT} \cdot R_M^3$, but non-dipolar terms are found to be significant (Uno et al. 2009; Johnson et al. 2012). These could indicate crustal fields or significant dynamo action close to the core/mantle boundary, which should be close to $0.8 R_M$. Missions to Venus have failed to detect a magnetic field of the planet. An upper limit for its dipole moment is 10^{-5} times the moment of the Earth or $0.35 \text{ nT} \cdot R_V^3$. The first unambiguous detection of an intrinsic field at Mars was achieved by the Mars Global Surveyor (MGS) mission (Acuna et al. 1999). The field strength varies between $\pm 200 \text{ nT}$ along the mapping orbit at 400 km height above the surface. These values suggest magnetizations of approximately 10^3 nT at the surface. It has been concluded that the Martian crust must be about ten times more intensely magnetized than the Earth's crust. The Moon does not have a dipole field at present, but large parts of the crust show remnant magnetization. The magnitude of the magnetization reaches values of up to 250 nT , much smaller than the magnetization of the Martian and the Earth's crust.

Definition

The magnetic field of a protostellar disk is a field that permeates the rotating disk of gas and dust about a protostar from which planets may form. Magnetic field lines rotate with the ionized component of the disk material and are subject to an instability that is the likely source of turbulence and viscous drag within a disk. This makes possible the inward accretion of mass from a disk onto its central protostar. It has also been suggested that magnetic forces are responsible for the observed ejection of high-velocity bipolar outflows from protostellar disks.

Overview

Interstellar and Planetary Magnetic Fields

Electrical currents flowing in conductors produce magnetic fields (“B fields”). Conductors in the cosmos include the metallic cores present in some planets and asteroids as well as the ionized gases, called plasmas, which pervade star- and planet-forming regions of interstellar space. Thus, Earth’s B field is attributed to currents in its iron-rich core. However, planetary magnetism is not universal: Mercury, Jupiter, Saturn, Neptune, and Uranus all have large-scale B fields, but Venus and Mars do not. Moreover, planetary magnetic fields vary widely, from ~ 1 mG (Mercury) to ~ 1 G (Earth, Jupiter) (Stevenson 2010). (1 G = 1 Gauss is a

standard unit of magnetic induction.) Within interstellar clouds, where star and planet formation takes place, field strengths ~ 10 – 100 μ G have been detected (Heiles and Crutcher 2005).

Magnetic fields tend to decay via the dissipation of currents by electrical resistance (“Ohmic dissipation”). In a material with electrical conductivity σ , the decay time is $t_{\text{decay}} = 4\pi\sigma L^2/c^2$, where L is a characteristic size or length scale for variations in B, and c is the speed of light. Setting σ to the conductivity of molten iron and L to the radius of Earth’s core gives $t_{\text{decay}} \sim 10^5$ years. Hence, persistent planetary B fields require some process to counteract Ohmic dissipation; this “dynamo mechanism” must be driven by convective motions in planetary cores, but the physics is complex and poorly understood. In contrast, the enormous scale of B fields in star- and planet-forming clouds makes them much longer lived: setting σ to a typical conductivity for interstellar cloud plasma and $L = 100$ AU (1 AU is the radius of the orbit of the Earth) yields $t_{\text{decay}} \sim 10^{11}$ year, which is almost ten times greater than the age of the universe.

Magnetohydrodynamics

Magnetic fields are mapped by magnetic field lines. At each point on a magnetic field line, the direction of the line indicates the direction of B and the spacing between adjacent field lines is inversely proportional to the magnitude of B. The motions of conducting liquids and plasmas (Cowling 1957; Parker 1979) can be described by the equations of magnetohydrodynamics (“MHD”). The motions of the conducting fluid dictate electrical currents and thus the B field. Magnetic forces feedback and affect the fluid motions, which makes the resulting dynamics generally complex. However, under conditions where Ohmic dissipation can be neglected, corresponding to large length scales and/or electrical conductivities, a much simpler picture arises. In this circumstance (“ideal MHD”), the magnetic field lines are frozen into and move with the plasma. The frozen-in field exerts tension and pressure forces on the fluid that are correlated with the curvature and spacing of the field lines.

Magnetic Fields and Planet Formation

Angular momentum conservation prohibits the direct formation of a star by gravitational collapse. A protostellar core (i.e., the part of an interstellar molecular cloud that gravitationally fragments and will ultimately form a star and planetary system) contracts first into a rotating protoplanetary disk or protoplanetary disk (Vicente and Alves 2005; Williams et al. 2005). The central star is built up later via the migration of disk material inward, a process which requires friction (viscosity) between matter in adjacent orbits with slightly different speeds. It is now generally accepted that magnetic fields are required to produce this friction, via a mechanism called the *magnetic rotational instability* (“MRI”) (Balbus 2010). Because field lines are dragged inward by collapsing core material, the B fields required by the MRI are plausible. The presence of dynamically significant B fields in protoplanetary disks is also indicated by observations of *bipolar outflows*, extended and highly collimated jets of material ejected parallel and antiparallel to the disk rotation axis (Reipurth and Bally 2001). According to *magnetocentrifugal outflow* models of bipolar outflows (Blandford and Payne 1982; Königl and Pudritz 2000), centrifugal forces fling plasma outward along magnetic field lines, which direct and collimate the flow. Bipolar outflows are extremely supersonic, producing *multifluid MHD shock waves* wherever they impact ambient material. Magnetic forces on the charged particles cause large differential velocities between ions and neutral molecules. Friction associated with the differential motions heats the plasma to $\sim 10^3$ K over an extended region (Draine et al. 1983). Shock heating opens chemical pathways which are closed in cold clouds, with unknown but potentially important consequences for prebiotic chemistry.

Magnetic Fields and Habitability

It is interesting that the only planet known to be inhabited also has a large magnetic field. However, it is well known that Earth’s B field ameliorates or eliminates effects that would be harmful to life. For example, the Sun emits a high-velocity stream of charged particles, the solar wind, which

flows through the solar system at hundreds of kilometers per second. A planetary atmosphere directly exposed to the solar wind would be partially or completely eroded. However, Earth is protected from solar wind erosion by its magnetic field, which fills a region (the magnetosphere) that largely excludes the solar wind (Lammer et al. 2010). The frozen-in magnetic field of the solar wind also protects the Earth, by sweeping galactic cosmic rays out of the solar system (Parker 1963).

Magnetic fields · Star formation

Definition

Interstellar magnetic fields are fields that thread the massive clouds of gas and dust in which stars are born. They exert magnetic forces on charged particles and can influence the large-scale stability of a cloud. Because magnetic forces do not act on neutral particles, self-gravity of the mostly neutral molecular gas in a cloud becomes greatly enhanced due to small-scale drift of neutrals with respect to charged particles. This creates dense localized regions known as protostellar cores, wherein self-gravity of the gas and dust exceeds restoring magnetic forces. Star formation is initiated by the subsequent gravitational collapse of a protostellar core.

Overview

Magnetic Fields in Space

Magnetic fields (“B fields”) are produced by electrical currents flowing in conductors. Conductors in space include ionized gases, called plasmas, which comprise stars and pervade interstellar clouds. Magnetism is universal in interstellar plasmas with field strengths $\sim 10\text{--}100\ \mu\text{G}$ in star-forming clouds (Heiles and Crutcher 2005).

Here $1\ \text{G} = 1\ \text{gauss}$ is a commonly used unit of magnetic induction B ; a typical value of B at the surface of the Earth is $0.5\ \text{G}$ (Stevenson 2010). Magnetic field lines map magnetic fields: at each point on a magnetic field line, the orientation of the line indicates the direction of B , and the spacing between adjacent lines is inversely proportional to the magnitude of B .

Magnetic fields tend to decay via the dissipation of currents by electrical resistance (“Ohmic dissipation”). In a material with electrical conductivity σ , the decay time is $t_{\text{decay}} = 4\pi\sigma L^2/c^2$, where c is the speed of light and L is a characteristic length scale for variations in B . The enormous scale of interstellar B fields makes them virtually immortal: setting σ to a typical conductivity for interstellar cloud plasma and representative $L = 1\ \text{pc}$ ($1\ \text{pc} = 3.26\ \text{light-years}$) gives $t_{\text{decay}} \sim 10^{18}$ years, about a hundred million times the age of the universe.

Magnetohydrodynamics

Magnetohydrodynamics (“MHD”) describes the motions of conducting plasmas (Cowling 1957; Parker 1979). The fluid motions dictate electrical currents and hence the B field. Since magnetic forces also affect the fluid motions, the dynamics are generally complex. However, under conditions where Ohmic dissipation is negligible, corresponding to large length scales and/or conductivities (such as in interstellar clouds), a simple picture emerges. In this regime (“ideal MHD”), the magnetic field lines are frozen into and move with the plasma. This frozen-in field exerts tension and pressure forces correlated with the curvature and spacing of the field lines.

Magnetic Fields and Star Formation

Magnetic fields play a crucial role in the support of interstellar [molecular clouds](#) against gravitational collapse. These clouds consist primarily of gaseous H_2 molecules and He atoms, along with much smaller relative abundances of other molecular species (such as CO and NH_3). They also contain interstellar dust grains, with $\sim 1\%$ of the cloud mass. Clouds are extremely cold ($\sim 10\ \text{K}$), having sizes from $\sim 1\ \text{pc}$ to $100\ \text{pc}$, mean particle densities $\sim 10^3\ \text{cm}^{-3}$, and masses $\sim 1\ M_{\odot}$ to

$10^5 M_{\odot}$ ($1 M_{\odot} = 1$ solar mass). Because the temperatures are so low, thermal pressure stresses are negligible compared to magnetic forces in clouds. Star formation in molecular clouds is observed to be very inefficient: less than 10% of a cloud's mass is converted by gravitational collapse into stars (Zuckerman and Palmer 1974). This inefficiency is due to internal B fields, whose supporting forces prevent wholesale cloud collapse; consequently, B fields regulate the rate of star formation (Mouschovias 1978; Shu et al. 1987). This is quantified by a cloud's *mass-to-magnetic flux ratio* (MtMFR), which is the ratio of its gravitational binding energy (proportional to the cloud mass squared) relative to its internal supporting magnetic energy (proportional to the square of the cloud's mean magnetic field strength). If the MtMFR is less than a critical value ("subcritical"), magnetic forces can support a cloud against its self-gravity. Conversely, if a cloud's MtMFR is greater than the critical value ("supercritical"), gravitational forces overwhelm magnetic forces and collapse can take place (Mouschovias and Ciolek 1999). Observations of Zeeman splitting of molecular OH lines, as well as polarimetric observations of the fluctuations in the direction of magnetic field lines in clouds (due to transverse MHD Alfvén waves that propagate along field lines), yield field strengths and MtMFRs in molecular clouds that are closely clustered around the critical value (Crutcher 2004), confirming large-scale magnetic support of clouds.

Even though molecular clouds are supported by internal B fields, star formation can still occur within them on small scales because clouds are weakly ionized. As stated above, a plasma can have a *frozen-in* magnetic field. But how effectively magnetic forces, which act only on charged particles, are transmitted to the bulk neutral matter (through charged-neutral particle collisions) depends on the abundance x_{cp} of charged particles relative to neutral particles (the plasma in molecular clouds is made up of cations such as Na^+ , Mg^+ , HCO^+ , electrons, and charged dust grains, which capture electrons on their surfaces). The outer layers of a cloud have $x_{cp} \sim 10^{-4}$, a value sufficient to ensure that collisions are frequent enough so that

supporting magnetic forces on the plasma are readily transferred to the neutrals, counterbalancing the compressing gravitational forces exerted on the neutrals. But $x_{cp} < 10^{-8}$ deep within a cloud, where matter is shielded from ionizing external UV photons. For x_{cp} values this low, neutral particles slip through the plasma and magnetic field lines (a process known as ► [ambipolar diffusion](#) (Mestel and Spitzer 1956)), increasing the mass in cloud interiors, but not the B field strength, as the field lines are "left behind" by the inwardly drifting neutrals. Hence, dense compact regions (mean densities $\sim 10^4 \text{ cm}^{-3}$, radii $\sim 0.1 \text{ pc}$) having MtMFRs greater than the critical value form inside globally supported clouds. These supercritical regions are *protostellar cores*, which dynamically collapse as a result of self-gravity. They are the localized sites within clouds where stars are born (Mouschovias and Ciolek 1999). MHD simulations of the formation and collapse of protostellar cores by ambipolar diffusion have been constructed for model molecular clouds, and their predicted magnetic field strengths and density and infall velocity profiles are consistent with multiwavelength observations of collapsing cores (Mouschovias and Ciolek 1999; Ciolek and Basu 2001). An alternative theory of star formation is that molecular clouds are short-lived objects formed by interstellar MHD turbulence. In this scenario, supercritical cores form randomly, via turbulent fluctuations, and collapse gravitationally to form stars (Mac Low and Klessen 2004).

the lines of magnetic flux enter and get out, and where the magnetic intensity is the highest. Due to the presence of a convecting liquid metal core, the interior of the Earth behaves as a giant dynamo, giving the Earth a magnetic field. This later is dipolar with an axis at a small angle to the Earth rotational axis, making the magnetic poles slightly offset from the geographic poles.

The magnetic polarity has changed with highly variable frequency through geological history. At times, the reversals are frequent, every few hundred thousand years or less, but in the mid-Cretaceous, the polarity remained constant for nearly 40 Ma. As the magnetic field is global, a reversal is strictly contemporaneous on any point on the planet. Consequently, it is used as a reliable chronometer, which led to the establishment of a *Geomagnetic Polarity Time Scale*.

The inclination of the magnetic field vector depends on the latitude; therefore, when recorded by magnetic minerals in rocks, it provides information about the latitude at the time the rock formed (paleomagnetism). Apparent polar wander curves are compilations of the positions of the magnetic poles as reconstructed from the minerals in strata of different ages from a single ► [continent](#) or smaller terranes; they trace the position of that tectonic element with reference to the position of the pole, assumed to be fixed. Such information provides evidence of relative plate movement from as early as the Archean.

Definition

Magnetite is a black, cubic iron oxide belonging to the spinel group. It is one of the most common magnetic minerals on Earth. The occurrence of two iron ions having different valences (2^+ and 3^+) occupying specific sites in the crystal structure causes a transfer of electrons generating the magnetic field. Magnetite occurs in almost all igneous and metamorphic rocks and in several types of sedimentary rocks, including banded iron formations. Crystals of magnetite are found in magnetotactic bacteria (e.g., *Magnetospirillum magnetotacticum*). Magnetic minerals were found in the Martian meteorite ALH 84001 and interpreted as the best evidence of indigenous bacterial activity (controversial) (e.g., McKay et al. [2003](#)).

MHD Magnetohydrodynamics

Definition

Magnetohydrodynamics (MHD) is a physical paradigm pertinent to describe the dynamics of electrically conducting fluids, such as plasmas, electrolytes, and liquid metals. MHD couples fluids dynamics with electromagnetism.

History

The first recorded use of the word *magnetohydrodynamics* (MHD) can be found in Alfvén (1942), who initiated this field. Hannes Alfvén received the Nobel Prize in Physics in 1970 for his work on MHD

Overview

Magnetohydrodynamics (MHD) is a set of postulates and theories that enables a synthetic description of the behavior of electrically conducting fluids subject to electromagnetic fields. Plasmas, liquid metals, electrolytes are example of electrofluids. Since plasma is by far the most abundant form of ordinary matter, MHD is a key paradigm in astrophysics, applying to stars and the Sun (formation, dynamo mechanism, atmospheric dynamics, eruptions, jets), star-planet interactions and in particular the stellar/solar winds, planetary magnetospheres, as well as protoplanetary disks, interstellar and intracluster media, active galactic nuclei, and possibly to the intergalactic regions.

The standard MHD description relies on several core hypothesis. First, MHD assumes a fluid description of matter, focusing on the macroscopic scales and relying on the continuous assumption, i.e., neglecting the specific behavior and properties of the particles that constitutes the fluid. Under the continuum assumption, macroscopic properties such as density, pressure, temperature, and bulk velocity are taken to be well-defined at “infinitesimal” volume elements – small in comparison to the characteristic length scale of the system, but large in comparison to the particles length scales. As a fluid theory, MHD also relies on the conservation of mass,

momentum, and energy. A second key hypothesis of MHD is the electric neutrality. At valid MHD scales, there shall be no free electric charge. MHD thus applies at a length scale that significantly exceeds the Debye length of the medium as well as at a temporal scale that is markedly larger than any specific particular timescale (e.g., frequency smaller than the plasma frequency).

The set of equations that describe MHD is a combination of the Navier–Stokes equations of fluid dynamics and Maxwell’s equations of electromagnetism. A key concept behind MHD is that the magnetic field that permeates the medium induces electric currents in the moving conductive fluid, currents that in turn affect the dynamic of the fluid, which retroactively modify the magnetic field itself. The Ohm’s law for conductive fluid links the electric field, with the magnetic field and the fluid velocity. The interplay between the magnetic field and the fluid dynamics is marked by the central role of the Lorentz force, through which the magnetic field affects the dynamics of the conductive fluid.

Several models of MHD can be used depending on the degree of complexity necessary to describe the studied system. One can cite: ideal MHD, resistive MHD, incompressible MHD, Hall MHD, multi-fluid MHD, Hartmann MHD, collisionless MHD, electron MHD, relativistic MHD, etc.

In ideal MHD, the fluid is treated as a perfect conductor (e.g., the electric resistivity is infinitely small). In such conditions, the Alfvén’s theorem states the fluid and the magnetic field are tied together, and have to move altogether: the so-called “frozen-in” condition. The magnetic flux through a co-moving surface is conserved in ideal MHD. Magnetic linkage is thus preserved which makes it possible to store magnetic energy by moving the fluid or the magnetic field. The stored energy can become available if the ideal condition breaks down, e.g., during magnetic reconnection: the magnetic field can then be rearranged and magnetic energy is converted to kinetic energy, thermal energy, and particle acceleration. While magnetic reconnection is by essence an MHD concept, its complete description lies beyond the MHD approximation

MHD waves are another major concept that derives from MHD. There are three main MHD wave modes: pure Alfvén wave, slow (shear) and fast (compressional) MHD waves. Alfvén waves are incompressible waves and do not appear in pure hydrodynamics. All the MHD waves have constant phase velocities for all frequencies and are thus dispersionless. Their role is heavily discussed in link with the heating of stellar corona and the acceleration mechanisms of stellar winds.

Definition

Intracellular magnetic crystal typically surrounded by a lipid membrane synthesized by magnetotactic organisms. Magnetosomes are chemically pure, have a narrow size range with species-specific crystal morphologies, and are arranged in chains (Bazylinski 1995; Spring and Bazylinski 2000). Magnetosomes are usually composed of the iron oxide ► [magnetite](#) (Fe_3O_4) or the iron sulfide greigite (Fe_3S_4). Membrane-bound magnetosomes form from invaginations of the inner membrane, and their position in the ► [cytoplasm](#) is supported by cytoskeletal filaments (Komeili et al. 2006), which suggests that magnetosome synthesis is a biomineralization process with strict biological control. Chains of magnetosomes are responsible for the passive orientation of ► [magnetotactic bacteria](#) along ► [magnetic field](#) lines (Blakemore 1975) (Fig. 1).

Overview

Bacterial magnetosomes have been a subject of intense research due to their relevance in such diverse fields as biomineralization, paleomicrobiology, technology, medicine, or astrobiology. Due to their small size and strong magnetic remanence, magnetosomes have also been used in nano- and biotechnological applications. Iron biomineralization is likely an ancient trait of terrestrial life, and iron minerals are common among organisms in the ► [Bacteria](#) and ► [Eukarya](#) domains. In particular, magnetosomes are often found in the fossil record (magnetofossils) in marine and lake sediments. The traits that characterize magnetosomes: chemical purity, size, morphology, and chain arrangement, all contribute to maximize the magnetic moment of the crystals, and the capacity of magnetotactic organisms to swim along magnetic field lines, and search efficiently for chemical gradients. These properties also confer magnetosomes a strong potential as ► [biomarkers](#), since non-biogenic magnetite and greigite crystals often fail to possess one or several of these traits. Biogenic minerals are also more resistant to chemical and physical weathering than

Magnetosome,

Fig. 1 Chains of magnetosomes extracted from lake sediments. The size, shape, morphology, and composition of the crystals reflect the biogenic origin. Crystals of different sizes are likely related to different species of magnetotactic bacteria. Scale bar represents 100 μm

organic biomarkers. For those reasons, magnetosomes have been proposed as a potential target in the search for life beyond Earth. Putative magnetite magnetosomes have been identified in the Martian meteorite ALH84001 and presented as evidence for relic biological activity on [Mars](#) (McKay et al. 1996), although these claims have been disputed.

Definition

The solar wind (SW) which flows across the solar system interacts with obstacles possessing a ► [magnetic field](#), an atmosphere, or a high internal conductivity. In the first case, generally concerning planetary obstacles, the magnetic pressure creates a cavity in the SW, where ► [plasma](#) motions are dominated by the planetary field; this region is called the “magnetosphere.” This magnetic bubble acts as a shield preventing the bombardment and escape of the planetary atmosphere. It also generates an intense electrical

activity, behaving as a natural charged particle accelerator. Planetary magnetospheres are contained in the Sun's sphere of influence (heliosphere), and in turn contain the magnetospheres of some of their satellites.

History

Auroras have been known since ancient times. In the nineteenth century, statistical measurements allowed localization of the northern auroral oval at 65–80° latitude, but its origin was not understood. Shortly after, Thomson discovered the electrons. This gave Birkeland the idea to use them to bombard a magnetized sphere in a rarefied atmosphere (vacuum chamber). He could then create and observe polar auroral lights as early as 1895–1910. He proposed that “polar magnetic storms” exist in the auroral zone, due to electron beams from the Sun. In the 1930s, Chapman and Ferraro proposed that “magnetic storms” are caused by solar plasma clouds interacting with the Earth's magnetic field. They proposed the existence of the dayside magnetopause (the outer boundary of the magnetosphere) at a few Earth radii based on the use of a reversed “image” of the terrestrial magnetic dipole to represent the compressed dayside terrestrial field. Thomas Gold proposed the name “magnetosphere” for the cavity, above the ionosphere, where the planetary magnetic field has dominant control over the motions of gas and fast charged particles.

The concept of solar plasma clouds remained vague until the suggestion by Biermann in 1951 of the existence of a permanent solar “wind” (flow of electrons, protons, and heavier ions escaping permanently from the solar atmosphere), in order to explain the second cometary tail, blueish, straight, and always antisolar (now known to be a plasma tail). In 1958, Parker proposed the first theory of the SW, which not only escapes the solar atmosphere but is accelerated up to supersonic speed into the interplanetary space. The first observational confirmation came with spacecraft observations in 1960.

Two years earlier, the Explorer 1 spacecraft discovered the Earth's radiation belts (of highly

energetic charged particles). In 1961, Dungey proposed the model of an open magnetosphere, still valid to describe the terrestrial magnetospheric dynamics, and involving elusive magnetic reconnection at the magnetopause. The magnetopause was actually observed as an abrupt magnetic field discontinuity in 1967. The auroral oval was first imaged from space in the 1980s.

In parallel, the discovery in 1955 of Jupiter's decimeter radio emission gave the first indications on the existence and intensity of the Jovian magnetic field, further refined by the discovery in 1958 of the synchrotron emission from Jupiter's radiation belts. In 1964, the statistical influence of Io on Jupiter's decimeter radio emission unveiled the first satellite-magnetosphere interaction.

Overview

Solar Wind Flow and Planetary Magnetic Fields

A central concept to the following discussion is that magnetic field (B) and plasma are “frozen” together, due to high plasma conductivity. Thus, in a frame where the magnetized plasma moves at velocity V , Maxwell's equations show that an electric field $E = -V \times B$ appears. It is equal to zero in the plasma frame, consistent with quasi-neutrality. Also, the fact the E and B are orthogonal implies that magnetic field lines are electric equipotentials. Potential drops between field lines are thus conserved along these field lines.

Being dominated by its bulk kinetic energy density, the SW carries away the solar magnetic field rooted in the Sun, generating the undulated surface (“ballerina skirt”) which separates the two magnetic hemispheres of the interplanetary medium. At Earth orbit, the SW has a speed $V \sim 400$ km/s (largely supersonic), a density of protons and electrons $N \sim 5$ cm⁻³, a temperature $T \sim 200,000$ K, and a weak magnetic field $B \sim 3$ nT.

Its interaction with a planetary obstacle depends on the existence of an intrinsic large-scale magnetic field, an ionosphere, and/or a high internal conductivity of the obstacle. In the first case, an abrupt boundary limits the region of

influence of the planetary magnetic field: the magnetopause.

There are six magnetized planets in the Solar System: Mercury, Earth, and the four giants. Their magnetic fields have a strong dipolar component as well as multipolar ones (of order $n = 2, 3, \dots$). These components are known up to $n \sim 14$ at Earth versus $n \leq 4$ for the other planets. Especially remarkable are the very weak dipolar field of Mercury (compared to the very large field of Jupiter), the largely tilted dipoles of Uranus and Neptune, and the purely axisymmetric Saturnian field (Table 1).

Magnetospheric Regions and Boundaries

The magnetosphere is the cavity bounded by the magnetopause, where the external SW pressure balances the internal planetary magnetic field pressure (Fig. 1). Electric currents circulate on the magnetopause, preventing magnetic field lines from crossing it (the field is tangential on the magnetopause). As a first approximation, there is no plasma exchange across the magnetopause. The dayside magnetopause radius lies

between a fraction to several tens of planetary radii from the planetary obstacle (Table 1). This “standoff” distance fluctuates with variations of the SW strength. Planetary magnetospheres are the largest structures in the solar system. If Jupiter’s with its 10^7 km radius was visible, it would appear larger than the full moon.

Because the SW flow is supersonic, a stationary bow shock develops ahead of the magnetopause. The intermediate region is the magnetosheath, whose thickness is 15–40% of the standoff distance, and where the flow is slowed down, heated and deflected around the obstacle, and the SW magnetic field lines “pile up” and are draped around it. Due to the flow and draping, the nightside magnetosphere is stretched and forms a magnetospheric tail up to several AU long. A singular region, the polar cusp, separates closed planetary field lines anchored to both hemispheres on the dayside from open lines swept back to the tail. A small fraction of the SW plasma penetrating the outer magnetosphere across the magnetopause may directly reach the polar ionosphere via the cusp. The cusp does not exist for

Magnetosphere, Table 1 Typical parameters of planetary magnetospheres. Comparison of the convection and corotation potential drops, as well as the ratio between

plasmasphere radius and magnetopause standoff distance tells which type of plasma circulation dominates magnetospheric dynamics

obstacles not possessing an intrinsic magnetic field, although an induced magnetosphere and a tail form due to magnetic draping.

Plasma Sources and Sinks

Although more rarefied than the surrounding SW, a magnetosphere contains plasma that may have various origins: the SW itself (via the cusp and diffusion/reconnection across the magnetopause), planetary ionospheres (through vertical diffusive

equilibrium), satellite exospheres (atmospheric escape from Titan, Io's volcanism, Enceladus' geyser plumes), surfaces of Mercury or icy satellites (through sputtering by SW of magnetospheric energetic particles), rings (sputtering, photo-dissociation, and ionization). These sources represent between a few hundred g/s to 1000 kg/s of H, He, and heavy (N, O, S, H₂O, ...) ions of temperatures between ~ 0.1 eV (ionospheric source) and ~ 100 eV (SW source).

The magnetospheric plasma is stored in various reservoirs including “boundary layers” (low-latitude on the dayside and tail mantle), plasma tori along satellite orbits, an equatorial plasma/current sheet at the center of the tail, and radiation belts. The total mass stored ranges from $\sim 10^7$ kg at Earth to $\sim 10^{10}$ kg at Jupiter.

Plasma sinks include absorption by the rings, satellites and auroral ionosphere, and interaction with neutrals atoms. At Saturn, the neutral nebula is 100 times denser than the magnetospheric plasma (dominated by H_2O ions), while the neutrals/ions ratio at Jupiter is only ~ 0.003 .

Plasma Circulation and Role of Ionosphere

If the magnetosphere was electro-magnetically insulated from external conditions, its plasma would simply be dragged by friction of the SW flow along the magnetopause flanks (over a thickness of few ion Larmor radii), generating two convection cells with antisolar plasma motion on the edges and solarward plasma return inside the magnetosphere. Such a circulation pattern is indeed observed at Earth, together with other phenomena inconsistent with the above “closed” magnetosphere model:

- Presence of energetic plasma inside the magnetosphere.
- Existence of a large-scale (dawn $\rightarrow$ dusk) electric field.
- Quasi-permanent circumpolar aurora at $65\text{--}80^\circ$ latitude, brighter on the nightside.
- Magnetospheric “activity” correlated with the direction of the interplanetary magnetic field (IMF) perpendicular to the ecliptic (B_z).

Hence the concept of an “open” magnetosphere, in which reconnection of the IMF with the planetary field at the magnetopause allows plasma entry. Dayside reconnection occurs at the magnetopause nose when B_z is oriented in opposition to the planetary magnetic field, so that their sum cancels out. This causes magnetospheric field lines to “open,” and then be transported to the tail above the poles, where they close after a new reconnection. Closed field lines then “redipolarize” (retract) toward Earth while a “plasmoid” is ejected tailward. In this cycle, proposed by Dungey (Fig. 2), the circulation pattern is similar as above, but it is associated with the observed dawn $\rightarrow$ dusk “convection” electric field ($E_{\text{conv}} \propto V_{\text{VS}} \times B_{\text{VS}}$) whose equipotentials are the solar-antisolar circulation lines. The second reconnection corresponds to a magnetic “substorm” during which energy is dissipated through charged particles heating and acceleration. Planetary rotation generates another large-scale, radial electric field ($E_{\text{corot}} \propto R\Omega \times B$), whose equipotentials are circles centered on the planet. Corresponding plasma circulation is “corotation.” Global magnetospheric circulation results from the superposition of convection and corotation, with a different relative importance at the various planets (Table 1).

The internal, corotation-dominated region is the dense plasmasphere fed by the ionosphere, where planetary field lines never open. Its radius is compared to that of the magnetopause in Table 1. At Jupiter and Saturn, the dominant centrifugal force drives outward plasma transport and forms a plasma disk where million-Ampere current flows and stretches the equatorial magnetic

Magnetosphere,

Fig. 2 Meridian sketch of the Dungey cycle of magnetospheric convection driven by the solar wind. Magnetic reconnection occurs in N1 and N2. The motion of a field line is followed from A to G along arrows ($\Rightarrow$)

Magnetosphere,

Fig. 3 Corotation-dominated plasmasphere (gray-shaded) and moons positions (red dots) in the magnetospheres of the Earth, Jupiter, and Saturn. Plasma corotation generates the equatorial current disk that stretches magnetic field lines. The tail X-line (where magnetic reconnection occurs) is located in the convection-dominated region at Earth, and in the corotation region at Jupiter, explaining why substorm-like events are related to the SW-magnetosphere interaction at Earth and to internal plasma mass-loading effects at Jupiter

field (Fig. 3). Corotation dominates so much at Jupiter that it modulates many magnetospheric phenomena (including radio emissions from which the planetary rotation period has been measured with 10^{-6} accuracy); a modified Dungey cycle exists, entirely driven by corotation (so-called “Vasyliunas cycle”). The magnetospheres of Earth and Mercury are convection-dominated, while Saturn is an intermediate case (Fig. 3). Interestingly, plasma circulation and the

degree of corotational control are – at first order – independent of the planetary magnetic dipole tilt (except at Uranus and Neptune where this tilt is extremely large).

Ionosphere-magnetosphere coupling ensures the closure of magnetospheric currents in a conducting spherical layer around the planet. Because magnetic field lines are electric equipotentials, the potential drops originating in the magnetosphere (with respect to the SW) are

Magnetosphere,

Fig. 4 Current generator associated with outward transport of the plasma produced by Io

mapped to the ionosphere along field lines. The magnetospheric circulation thus causes the existence of high-latitude ionospheric convection cells. Due to converging field line geometry, ionospheric electric fields are larger than their magnetospheric counterparts, while plasma velocities are smaller. At Mercury, the nature of the process(es) ensuring magnetospheric current closure is still a puzzle.

Current Generators

Large-scale closed current circuits exist in planetary magnetospheres, each related to a specific generator:

- SW-driven convection drives high-latitude currents at the boundary between open and closed field lines that close into the polar ionosphere.
- In the Jovian system, outward transport of the plasma from Io generates a radial current (J), which closes into the ionosphere via magnetic-field-aligned (or “Birkeland”) currents. The Lorentz force ($J \times B$) associated with this radial current accelerates the magnetospheric equatorial plasma to corotation speed, while slowing down the ionospheric plasma.
- Ganymede’s intrinsic magnetic field is in permanent Dungey-like reconnection between with the Jovian field sweeping past the satellite.
- Unmagnetized satellites swept past a fast-rotating magnetosphere “see” part of the corotation electric field in their rest frame. When they have an ionosphere, like Io or Titan, a current is driven by this electric field that

again closes into the planetary ionosphere via field-aligned currents (Fig. 4).

All these currents dissipate energy in the magnetosphere and the ionosphere. Furthermore, when a strong current is forced through a rarefied plasma, it leads to electron acceleration. A fraction of the magnetospheric plasma is thus accelerated to keV/MeV energies through various processes.

Aurora

Polar auroras are the most spectacular sign of magnetospheric activity (Fig. 5). They are produced by the radiative de-excitation of atmospheric atoms and molecules, emitting green and red oxygen lines on Earth, and ultraviolet H and H₂ bands on Jupiter and Saturn. These atmospheric constituents are collisionally excited by energetic electrons ($\sim 1\text{--}10$ keV) accelerated in the magnetosphere by the above processes. Joule heating also produces infrared auroral emissions, while intense radio emissions are produced along magnetic field lines above the auroras.

In a convection-dominated magnetosphere (as Earth’s), auroral ovals are located at the boundary of open and closed field lines. They are the magnetic projection onto the atmosphere of reconnection sites, especially the tail one, where accumulated energy and magnetic flux are suddenly released during substorms (typically several times a day). Note that auroras are by no means related to direct SW entry in the cusps. In a corotation-dominated magnetosphere (as Jupiter’s), auroras map the region where corotation breaks down due

Magnetosphere, Fig. 5 Earth auroras (*top*) seen from the ground (*left*), the space shuttle (*center*), and from a spacecraft (*right*). The auroral oval corresponds to the boundary between open and closed field lines. Jovian

auroras (*bottom*): the oval corresponds to the corotation breakdown, the isolated spots to the magnetic footprints of Io, Ganymede, and Europa

to insufficient momentum transfer from the ionosphere to the magnetosphere, in spite of maximum intensity field-aligned currents.

Auroral-like emissions are also produced at the planetary magnetic footprints of satellites, either magnetized or possessing an ionosphere (Fig. 5). Auroras (visible, UV, IR, radio) are the image of magnetospheric activity projected along magnetic field lines onto the atmosphere as on a TV screen.

Concluding Remarks and Future Directions

Planetary magnetospheres are complex electrodynamic machines, both charged particle accelerators and shields protecting the atmospheres against cosmic rays, solar eruptions, and evaporation. They are also plasma physics laboratories, displaying universal processes operating in very diverse environments (depending on object size, distance to Sun, magnetic field intensity, rotation, plasma sources, etc.). Each solar system magnetosphere has specific characteristics, which makes comparative study essential. Expanding these studies to exoplanet-star plasma interactions is very appealing. Hot Jupiters (close-in orbiting giant exoplanets), enduring high stellar wind pressure, might have compressed magnetospheres.

Alternately, they might be interacting with their parent star, via reconnection if they are magnetized (like Ganymede with Jupiter, or interacting magnetic binaries) or via currents and Alfvén waves (like Io with Jupiter) if they are unmagnetized. They are expected to produce intense electromagnetic emissions, especially in the radio range, which are being actively searched for.

magnetic crystals called ► [magnetosomes](#), which can be composed of the iron oxide magnetite or the iron sulfide greigite. Magnetite-producing magnetotactic bacteria are typically microaerophilic, whereas greigite-producing magnetotactic bacteria are usually strict anaerobes. Their magnetotactic response allows this type of bacteria to navigate efficiently along chemical gradients. Magnetotaxis is not a taxonomic trait, and has been described in many phylogenetic groups comprising diverse morphologies, including coccoid, rod-shaped, spirilloid, and even multicellular (Fig. 1).

History

Magnetotactic bacteria were first observed by Salvatore Bellini, from the University of Pavia, in 1963 in samples from drainage water. Richard P. Blakemore described them in marsh sediments and first coined the term “magnetotactic” (Blakemore 1975). Since then, magnetotactic bacteria have been observed in almost every aquatic environment, including polar lakes, and several strains have been grown in pure cultures in the laboratory. This has allowed for comprehensive

Magnitude

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Keywords

Brightness · Flux · Photometric system · Star

Definition

In astronomy, the magnitude is a measure of the brightness of a celestial object expressed on a logarithmic scale.

Overview

The magnitude scale, which comes from the visual astronomy, is only defined in the optical to mid-infrared wavelength range (300 nm to 20 μm); in other parts of the electromagnetic spectrum (X, radio, etc.) physical units are used, such as W m^{-2} , Jy, etc. The measure is generally defined for a specific filter, that is, for a given wavelength and a given bandpass. A set of filters corresponds to a photometric system, one of the most widely used being the Johnson system. With no other indication, the term magnitude refers to the magnitude in the V (“visible”) band of the Johnson system ($\lambda = 550 \text{ nm}$; bandpass = 89 nm). The magnitude scale is a relative scale, the reference of brightness being the star Vega. It is thus a quantity with no units. The magnitude of a given object whose measured flux in a given filter X is F_X is given by the expression: $m_X = -2.5 \log 10(F_X/F_X[\text{Vega}])$.

The coefficient -2.5 as a factor in the logarithm of the brightness was chosen by Norman R. Pogson in the nineteenth century, so as to link this scale to the one used by ancient Greek astronomers when estimating qualitatively the star’s brightness.

Note that the lowest magnitudes refer to the brightest objects: for instance, Sirius, the brightest star, has a magnitude $V = -1.46$, while the faintest stars seen by a trained unaided eye is of magnitude 6 and the dimmest objects that very large telescopes are able to catch are typically of magnitude 27.

The magnitude scale has several avatars: the absolute magnitude, the ► [bolometric magnitude](#), and the ► [color index](#). It is also used to measure the dimming by an absorbing medium, for instance, that introduced by the atmosphere or by the interstellar extinction. In this last case, the difference in magnitude is noted as A_V .

Magnitude, Absolute

Daniel Rouan
LESIA, Observatoire Paris-Site de Meudon,
Meudon, France

Definition

The absolute magnitude of a star or any celestial object is the apparent magnitude that the object would have if it were at a distance of 10 pc or 32.6 light-years from Earth. Within the solar system, the definition differs; it is the magnitude an object would have when put at a distance of one Astronomical Unit from Earth.

Main Sequence, Star

Nikos Prantzos
Institut d'Astrophysique de Paris, Paris, France

Definition

The region of the ► [Hertzsprung-Russell diagram](#) occupied by stars during their central H-burning phase is called the main sequence. It is a quasi-diagonal band, running from low to high values of stellar luminosities and effective temperatures.

The position of a star in that band is mostly determined by its mass (through the ► [mass-luminosity relation](#)), and to a much smaller degree by its metallicity (where astronomers refer to all elements heavier than helium as “metals”; less metallic stars being hotter) and age (older stars being more luminous). Since H-burning (fusion of hydrogen to helium) is the longest period in a star's life, about 90 % of all stars are on the main sequence. In star clusters, the upper end of the main sequence is truncated since the more massive stars have evolved toward the red giant branch (or already died); the position of this truncation provides a means to infer the cluster's age.

Definition

Manganese (Mn) is a transition metal present at trace levels in the modern ocean where it cycles between three oxidation states, +2, +3, and +4. Mn is a cofactor in enzymes critical for life, including the oxygen-evolving complex of photosystem II involved in oxygenic photosynthesis and superoxide dismutase (SOD) that degrades oxygen radicals responsible for oxidative stress. Mn(IV) forms a suite of Mn oxide minerals found within marine ferromanganese crusts and nodules that scavenge trace metals and record paleoredox conditions throughout Earth's history. Mn oxides form within a wide range of environments, including deserts, and on Mars as rock varnish and crusts.

Overview

Manganese (Mn) oxides are widespread on Earth, occurring as particles or grain coatings, rock varnish, cave deposits, and ferromanganese crusts and nodules. Rocks and sediments enriched in Mn oxides have been observed on Mars (Lanza et al. 2014) and in early Earth strata (Crerar et al. 1980; Krinsley et al. 2009); yet, little is known about the modern or paleo-environmental behavior of Mn. Mn oxides are receiving increasing attention as useful paleoredox indicators since oxidation of Mn(II) to Mn(III,IV) oxides requires oxidants with high redox potential. Unlike iron, oxidation of Mn(II) by molecular oxygen (O₂) is thermodynamically prohibited in the absence of (in)organic catalysts (Luther III 2010). Further, the budgets and isotopic fractionation of many trace metals (e.g. vanadium, copper, nickel, molybdenum, and thallium) are partially controlled by their strong adsorption to Mn oxides, rendering Mn oxides a primary driver of the isotope composition of important trace element paleoproxies (Siebert et al. 2003).

The presently known pathways for Mn(II) oxidation to Mn(III,IV) oxides require the presence of O₂ or derivatives of oxygen, specifically reactive oxygen species (ROS). Most cases/examples of Mn(II) oxidation on Earth are also believed to be a consequence of direct or indirect microbial activity. Three general pathways exist for the oxidation of soluble Mn(II) to insoluble Mn(IV) and ultimate precipitation as Mn oxide minerals. First, Mn(II) can be oxidized by O₂ when complexed to mineral surfaces or organic ligands (Duckworth and Sposito 2005). Second, some bacteria directly mediate Mn(II) oxidation using enzymes such as multi-copper oxidases (Butterfield et al. 2013) even in the presence of micromolar levels of O₂ (Clement et al. 2009). Third, Mn(II) oxidation to Mn oxides occurs via reaction with the ROS superoxide of both abiogenic (Learman et al. 2013) and biogenic (fungal, bacterial) origin (Hansel et al. 2012; Learman et al. 2011; Tang et al. 2013). Unlike O₂, oxidation of Mn(II) to Mn(III) by superoxide is rapid even in the presence of low superoxide and Mn levels (pM-nM) (Hansard et al. 2011) and is thermodynamically favored over a broad pH range (Luther III 2010).

At present, evidence is lacking for Mn(II)-based chemolithotrophy and instead Mn(II)-oxidizing bacterial isolates are obligate aerobic heterotrophs that do not gain energy or acquire a known physiological benefit from oxidizing Mn(II). Regardless of the abiotic or biotic pathway the oxidation of Mn(II) to Mn(IV) oxides occurs via a one electron transfer process leading to the formation of a Mn(III) intermediate (Johnson and Tebo 2008; Learman et al. 2011; Webb et al. 2005). The absence of observed Mn-based metabolisms may therefore stem from the energetic constraint imposed by the first electron transfer step from Mn(II) to Mn(III). Mn(III) has historically been regarded as environmentally unimportant due to its instability in solution in the absence of organic complexing ligands. More recently, significant levels of soluble Mn(III) ligand complexes (Mn(III)-L) were measured in marine systems spanning oxic to anoxic (Madison et al. 2013; Oldham et al. 2017). The fate of Mn(III)-L and subsequent reaction pathway from Mn(III) to Mn(IV) is less clear and may involve

further (a)biotic oxidation to Mn(IV) or disproportionation to Mn(II) and Mn(IV). Alternatively but currently unproven, this Mn(III)-L could provide an energetically favorable electron donor for Mn based chemolithotrophy or phototrophy. The ultimate precipitation and stabilization of Mn oxides within environmental systems is nevertheless at odds with Mn(IV)-reducing processes, including photoreduction, reaction with the ROS hydrogen peroxide, and anaerobic respiration by bacteria (Learman et al. 2013; Sunda and Huntsman 1994). Mn oxide formation and preservation may in fact require stabilizing organic templates (Estes et al. 2016). Together, Mn oxides are recorders of the surrounding geochemistry during their formation, and thereby provide a window into the geochemistry of past environments on Earth and elsewhere.

Definition

Manganese (Mn) is the third most abundant transition metal in the Earth's crust, where it is about 56 times less abundant than iron. Nonetheless, the abundance of Mn is ~60% greater in oceanic compared to continental crust. Thus, Mn is distributed widely throughout the global ocean, where it cycles among three dominant oxidation states – Mn²⁺, Mn³⁺, and Mn⁴⁺ – via reduction, oxidation, and disproportionation reactions. The reduction of Mn(III)-ligand complexes and Mn (III, IV) oxides is mediated by a number of abiotic and biotic processes involving either the direct or indirect activity of microorganisms. The reduction of Mn impacts the distribution of numerous other trace metals within the modern ocean and rock record.

Overview

Manganese (Mn) is distributed broadly throughout the modern global ocean and rock record on the Earth. Weathering of Mn-bearing primary minerals and hydrothermal vent fluids are dominant sources of Mn(II) to the ocean. Despite the fully oxidized Mn(IV) species being thermodynamically favored in oxic seawater, aqueous Mn(II) and Mn(III) are the dominant species in the ocean (Bruland et al. 1994; Oldham et al. 2017). This distribution is due in large part to the rapid photoreduction of Mn oxides in the photic zone (Sunda and Huntsman 1994) and the thermodynamic and kinetic constraints on the first oxidation step (Mn²⁺ to Mn³⁺) via O₂ (Luther III 2010). Deeper in the water column and within marine sediments, oxidation of Mn (II) and Mn(III) via direct and indirect microbial activity leads to the formation of Mn(III,IV). Here, as Mn(IV) is not stable in solution, Mn precipitates as single or mixed valence Mn oxy(hydr)oxides. Manganese oxides are often found as particles below the photic zone (Johnson et al. 1996) and in surface sediments within deep fjords or ocean basins, where geochemical focusing leads to their accumulation (Thamdrup et al. 1994). At the sediment interface

at abyssal depths, a significant portion of Mn is concentrated in ferromanganese concretions (nodules) and crusts (Horn et al. 1972).

A wide diversity of facultative or obligate anaerobic microorganisms couple the oxidation of organic carbon to the reduction of soluble Mn(III) complexes (Kostka et al. 1995) and solid-phase Mn(III,IV) oxides (Myers and Nealson 1988). In fact, microbial Mn reduction can be a dominant control on carbon oxidation within marine sediments (Thamdrup et al. 2000). For instance, microbial Mn reduction has been attributed to 25–99% of carbon oxidation within Mn-rich coastal marine sediments (Canfield et al. 1993a,b; Thamdrup et al. 2000). Despite observations of unique Mn(IV)-reducing communities within marine sediment incubations (Vandieken et al. 2012), at present there are no obligate Mn(IV)-reducing microbial isolates in culture. Instead, organisms capable of Mn reduction typically have the capacity to utilize a broad range of electron acceptors, including other metals, and at times oxygen, nitrate, various sulfur species, and/or organic compounds (e.g., fumarate).

The (a)biotic reduction of Mn(III,IV) oxides is coupled also to other elemental cycles, including nitrogen, trace metals, and sulfur. For instance, the reduction of Mn oxides has been proposed to play a role in the anaerobic oxidation of methane (Beal et al. 2009) and ammonium (Thamdrup and Dalsgaard 2002). However, the exact reaction pathways and organisms involved, and whether these reactions can be coupled to energy gain within one organism or involve a consortia remain unresolved. Further, Mn(III,IV) oxides serve as potent chemical oxidants at oxic-anoxic interfaces reacting rapidly in the absence of O₂, most notably with sulfide (Dellwig et al. 2012), iron(II) (Postma and Appelo 2000), nitrite (Luther and Popp 2002), and iodide (Fox et al. 2009). The reduction of Mn oxides also indirectly influences trace metal cycling through the liberation of a suite of trace metals that are adsorbed on and/or coprecipitated with the oxide. Indeed, Mn oxides, which have been coined the “scavengers of the sea,” sequester disproportionately high levels of trace metals and nutrients in comparison to the surrounding

seawater (Goldberg 1954), making these oxides a dominant control on the concentration and also stable isotope composition of trace metals in the ocean.

Mantle

Nicholas Arndt

Emeritus Professor, ISTerre, University Grenoble Alpes, Grenoble, France

Definition

The *mantle* is the part of the Earth or of other rocky planets which lies between the outermost solid crust and the metallic core. On the icy planets of our Solar system, the mantle is the part that lies between the layered atmosphere and the ice-silicate core. On Jupiter, the mantle is made of two layers: one liquid and one metallic hydrogen. On Earth, it is mainly composed of silicate minerals, whose nature changes depending on the pressure (or depth). In the upper mantle, between the base of the crust and the transition zone at about 660 km, the principal rock type is peridotite composed of olivine, orthopyroxene, clinopyroxene, and an aluminous phase (plagioclase, spinel, or garnet). In the lower mantle, these minerals convert to denser phases such as Mg- or Ca-perovskite and magnesiowüstite. The terrestrial mantle is solid except in shallow zones of partial melting beneath mid-ocean ridges or in hot spots, and perhaps at the core-mantle boundary. The mantle convects at different scales, which is an important process driving plate tectonics and the subsequent exchange of matter and energy at the surface of the Earth. These exchanges create chemical gradients and thermodynamic potentials that help drive biosynthesis near hydrothermal-vent biological communities.

Hotspot

Definition

Mantle plumes are columns of hot buoyant ► [mantle](#) that originate from a thermal boundary layer deep in the Earth. The most likely source of plumes is the core-mantle boundary at a depth of 2900 km, although it has been suggested that small plumes may originate from the boundary between the upper and lower mantle at 670 km depth.

History

The Canadian geologist Tuzo Wilson suggested in 1963 that the age progression in the Hawaiian Islands was due to the oceanic lithosphere moving over a stationary “hot spot” in the mantle. Seven years later, the US geophysicist Jason Morgan recognized that Wilson’s hot spots were plumes of hot mantle that originated from the thermal boundary layer above the core.

Overview

Plumes must originate from thermal boundary layers, which in the case of Earth’s mantle is the core-mantle boundary or perhaps the boundary between lower and upper mantle. The core is hotter than the overlying mantle and it cools by conduction to the mantle, forming an

approximately 100 km thick boundary layer of hot, buoyant material. Before the buoyant mantle can rise at an appreciable rate, it must acquire enough buoyancy to overcome the viscosity of the cooler overlying mantle. As a consequence, starting plumes have a large head. Upwelling continues along the narrower high-temperature, low-viscosity pathway of the tail. The narrow diameter of mantle plumes conduits (<50 km) is a result of the strong temperature dependence of mantle viscosity. Some models predict that plume heads initially have a diameter of about 200 km but that they grow by entrainment as they rise, reaching a diameter of 1000 km at the top of the mantle. Here, they flatten to form disks about 2000 km across. Other models predict more complex geometry and dynamics. If a plume head is compositionally heterogeneous, it can stall at the upper mantle-lower mantle boundary and give rise to one or more smaller, secondary plumes. The plume heads melt to form flood ► [basalts](#) when they ascend beneath continents or oceanic plateaus when they ascend beneath oceans. Flood basalts and oceanic plateaus have observed lateral dimensions of 2000 by 2000 km, similar to the predicted dimensions of a flattened plume head. The Siberian and Deccan Traps, which erupted 250 and 65 Ma ago, respectively, are examples of continental flood basalts, and the 122 Ma old Ontong Java plateau is an example of an oceanic plateau. Eruption is usually rapid and in these three cases probably took less than 1 Myr. Flood basalts are the most voluminous eruptions in the geological record. It is not by coincidence that the two largest examples, the Siberian and Deccan Traps, correlate with the two biggest mass extinctions, the Permian-Triassic and the Cretaceous-Tertiary extinctions. More recent flood basalts, like the Deccan Traps, are connected by a chain of volcanic islands (Chagos-Laccadive ridge) to the current position of a plume or hot spot, which is now situated below Reunion Island. The island chain formed by melting the plume tail and produced a track across the sea floor because motion of the plate transported the flood basalt away from the current position of the plume. Large planetary volcanic structures, such as ► [Olympus Mons](#) on Mars and Artemis on Venus, have also been attributed to mantle plumes.

Keywords

Terrestrial mantle · Volatile elements · Noble gases · Water · Carbon · Nitrogen

Definition

Volatile elements are elements that are in gaseous, liquid, or icy form at temperature and pressure conditions of the Earth's surface. ► [Mantle](#) volatiles are those elements present in the terrestrial mantle. These are mainly hydrogen (water), carbon, nitrogen, and noble gases. Sulfur species and halogens are also transferred from the mantle to the Earth's surface in gaseous form and are considered as mantle volatiles. These elements were trapped in the solid Earth during terrestrial accretion and were exchanged with the Earth's surface through mantle-derived volcanism and plate ► [subduction](#). Some of them (e.g., helium and neon) have never seen the surface and are called primordial volatiles.

Overview

Mantle-derived basalts and volcanic gases contain volatile elements such as water, carbon, nitrogen, sulfur halogens, and noble gases, whose isotopic composition indicates that they do not originate from the local crust or atmosphere/hydrosphere but come from the underlying mantle. In particular, helium in mantle-derived volcanic rocks and gaseous emanations is enriched in the rare isotope ^3He , otherwise abundant in extraterrestrial material. Likewise, mantle neon has an isotopic composition different from that of the Earth's atmosphere and comparable to values found in the Sun or in material irradiated by the solar wind. The stable isotopes of H and N indicate that volatile elements in Earth were trapped from a source sharing similarities with primitive ► [meteorites](#). Some of the noble gas isotopes are formed from extant and extinct radioactive decays, allowing quantification of mantle degassing through time. Comparison of the relevant isotopic ratios of the mantle and of the atmosphere indicates that mantle degassing was very active during the first tens to hundreds of Ma, resulting in the development of a stable atmosphere early in Earth's history. In contrast to noble gases, major volatiles (H, C, N, S) have been exchanged between the

mantle and the Earth's surface because they can be trapped as solids in minerals and reinjected into the mantle at subduction zones.

Mantle degassing takes place at mid-ocean ridges and at mantle plume localities, during magma generation. Volatile elements originally trapped in mantle minerals enter preferentially the magmas and degas to the atmosphere and hydrosphere during volcanic eruptions. Mantle ingassing occurs at subduction zones where the hydrated and carbonated oceanic plates are plunging into the mantle. Some of volatile elements are expelled during dehydration of plates and released back to the surface through arc magmatism, but a significant fraction of volatile elements survives dehydration and returns to the mantle, possibly at the core-mantle boundary. The mantle is a well-degassed reservoir: It contains $\sim 10^{-3}$ times less volatiles than primitive (► [chondrite](#)) meteorites. This depletion is the result of a combination of processes: volatile element depletion of the Earth's building blocks impacts degassing of accreting bodies and mantle degassing through convection and magmatism. It is possible that mantle volatiles were acquired during the late accretion (i.e., after terrestrial differentiation) of a small fraction of volatile-rich material, a process known as the "late veneer" accretion.

Definition

The oxidation state of the mantle generally refers to the redox conditions prevailing in the mantle. The mantle redox state is controlled by the oxygen fugacity, which can be delimited using specific pairs of *redox buffers* (i.e., an assemblage of minerals or compounds that constrains oxygen fugacity as a function of temperature). Being iron the Earth's most abundant element having multiple valences, usually the measurement of the $\text{Fe}^{3+}/\Sigma\text{Fe}$ ratio in rocks and minerals allows defining the oxygen fugacity and thus the oxidation state of the mantle.

Overview

Determining the oxygen fugacity ($f\text{O}_2$) of Earth's mantle is of primary importance because it

controls the speciation of C-O-H-bearing fluids and melts. This in turn can have an effect on the mantle solidus and properties of the resulting liquids, i.e., influencing, for example, magma degassing styles (Frost and McCammon 2008). In other words, it affects the speciation and mobility of volatile elements in the interior and has control on the character of degassing species from the Earth since the planet's formation, i.e., the secondary atmosphere composition of the Earth (Stagno et al. 2013).

Mantle oxygen fugacity can be evaluated by oxythermobarometry measurements, mainly by measuring the $\text{Fe}^{3+}/\Sigma\text{Fe}$ ratio in rocks and minerals from the mantle: basalt glasses from mid-ocean ridges (MORBs; e.g., Cottrell and Kelley 2011) and oceanic islands (OIBs; e.g., Ballhaus 1993), and spinel- and garnet-bearing peridotites for the upper mantle (Canil et al. 1994); perovskite (CaTiO_3), ferropericlasite (Mg, FeO), or garnets as inclusions in diamonds for the transition zone down to the lower mantle (e.g., Stagno et al. 2013; Kaminsky et al. 2015; Kiseeva et al. 2018) (see also Frost and McCammon 2008 for a complete review on the subject).

Typical mantle oxygen fugacities recorded by spinel-bearing peridotite rocks originating at depths of 30–50 km in the mantle ranges from 3 log units below to 2 log units above the $f\text{O}_2$ imposed by the fayalite–magnetite–quartz (FMQ) buffer equilibrium ($f\text{O}_2 \approx 10^{-8.5}$; Frost and McCammon 2008):

The $\log(f\text{O}_2)$ value is defined as the logarithmic difference between measured oxygen fugacity conditions and those imposed by the FMQ buffer and the units are termed as ΔFMQ .

At depths of 200–250 km, subducted lithospheric mantle $f\text{O}_2$ ranges from -4 to -6 log ΔFMQ units (Tumiati and Malaspina 2019). At the transition zone (depths >410 km) the $f\text{O}_2$ is -0.26 to $+3$ log ΔIW units, these latter defined as relative to the Fe–FeO (iron–wüstite) or IW oxygen buffer ($f\text{O}_2 \approx 10^{-12}$) (Kiseeva et al. 2018).

Mantle redox conditions might have varied with time. The Hadean and the Archean lithospheric mantle could have been more reduced than the present day ($f\text{O}_2$ within the FMQ buffer), with oxygen equivalent to the iron–wüstite (IW) buffer (Kasting et al. 1993). This is an important point to be determined because the mantle oxidation conditions have certainly had a role in the type of degassing volatile species that composed the primitive secondary atmosphere. Modern volcanic gases are relatively oxidized: typical $\text{H}_2/\text{H}_2\text{O}$ and CO/CO_2 ratios are ≈ 0.01 and ≈ 0.03 , while reduced species such as NH_3 and CH_4 are virtually absent (Holland 1984). Their composition is consistent with that predicted for equilibrium with a magma whose oxygen fugacity is close to that of the FMQ equilibrium. In the Archean, more reduced gases, predominantly H_2 and CO in equilibrium with a magma whose oxygen fugacity was close to that of the IW buffer, might have dominated the atmosphere and acted as an important O_2 sink (Kump and Kasting 2001). The oxygen sink, by oxidation of the reduced volcanic outgassing flux, could have overwhelmed the photosynthetic O_2 source, contributing to maintain a reducing atmosphere up to the Archean/Proterozoic boundary. However, variations in the contents of vanadium (V) and other redox-sensitive elements in Archean lavas and peridotites suggest that the oxygen fugacity in the Archean mantle was a little different (Berry et al. 2008) or more oxidizing than that of the modern mantle (Canil 2002).

It is known that the mantle above subduction zones is more oxidized than is oceanic or ancient cratonic mantle (e.g., Brandon and Draper 1996). Oxidation could have caused by ingassing of oxidized volatile species and/or an agent ranging in composition from solute-rich hydrous fluid to water-bearing silicate melt (Brandon and Draper 1996). Recent studies based on the isotopic evolution of xenon in the mantle has suggested that volatile recycling was minimal until 2.5 Ga ago, which roughly corresponds to the period (3.0–2.5 Ga) when modern plate tectonics became dominant on Earth (e.g., Mukhopadhyay and Parai 2019; Perron and Moreira 2018).

Mare Plains

- [Mare, Maria](#)

Mare, Maria

Stephan van Gasselt
Planetary Sciences and Remote Sensing, Institute of Geological Sciences, Freie Universität Berlin, Berlin, Germany

Keywords

Basaltic flood volcanism · Lava · Mercury · Moon · Titan

Synonyms

[Basaltic flood plains](#); [Mare plains](#)

Definition

Maria are medium- to large-size mostly circular flat-floored low-albedo plains on the Earth's Moon and the Saturnian ► [satellite Titan](#). On the ► [Moon](#) maria are formed by basaltic flood volcanism and are predominant on the lunar nearside. On Titan, maria are postulated to be filled with liquid ► [hydrocarbon](#) compounds, in particular ► [methane](#) and ethane.

Overview

The term mare originally referred to large-size low-▶ [albedo](#) features on the Moon. Lunar mare are lava plains characterized by low-viscosity basaltic flood lava. The use of the term mare has been extended to other terrestrial bodies in the solar system, especially to Titan where maria are radar-dark features that are assumed to be large lakes of liquid hydrocarbon compounds.

On the Moon, the term *mare basin* refers to an impact structure filled by flood lava. Although lunar maria and impact basins are spatially related, mare materials were emplaced later when compared to impact basins formed during the Nectarian heavy bombardment period, as radiometric ages of samples and chronostratigraphic relationships demonstrate. Radiometric sample ages as well as crater-size-frequency model ages of lunar maria are primarily in the range of 3.16–4.2 Gyr but may be as young as 1.2–1.5 Gyr.

Despite a homogeneous impact basin distribution on the Moon, maria are usually found on the near side, which is considered to be the result of the Moon's crustal dichotomy and is often associated with high mass concentrations (MASCONS) and large gravitational anomalies.

Maria are rich in geologic features characteristic of emplacement of flood lava, such as lava flows, lobate flow scarps, volcanic domes and cones, lava ponds, sinuous and arcuate rilles, and wrinkle ridges.

Maria were sampled during the Luna and Apollo missions, and the returned samples as well as remotely sensed spectra showed a mafic (Mg/Fe) composition with modal plagioclase contents of up to 50 wt% and high FeO contents of up to 20 wt%, as well as high Ca/Al ratios when compared to lunar highland rocks. They show varying amounts of Ti, reaching up to 15 wt% TiO₂ for *high-Ti* mare basalts. They are considered to be produced by partial melting of mafic rock in the lunar ▶ [mantle](#) at depths of up to 500 km.

On Saturnian satellite Titan, maria refer to flat, low-albedo, radar-dark areas investigated in the infrared and radar spectrum by the ▶ [Cassini](#) Spacecraft in 2006–2007. They are considered to be formed by liquid ▶ [hydrocarbons](#), especially methane. Ligeia Mare has a diameter of 500 km.

Margulis, Lynn

Ricardo Amils
Centro de Biología Molecular Severo Ochoa
(CSIC-UAM), Universidad Autónoma de Madrid, Madrid, Spain

Overview

Lynn Petra Alexander (March 5, 1938 – November 22, 2011) pioneered modern evolutionary biology with her revolutionary theory

that symbiosis was responsible for the origin of the eukaryotic cells. She also developed with James Lovelock the concept that Earth functions as a self-regulating system, known as the Gaia hypothesis.

Born in Chicago, she graduated in Biology at the University of Chicago and obtained her PhD at Berkeley University in 1965. Soon after she moved to Boston University where she taught biology for 22 years. Finally, in 1988, she moved to Amherst as she was appointed Distinguished Professor of Botany, later of Biology and finally of Geosciences at the University of Massachusetts.

Her seminal paper “On the Origin of Mitosing Cells” (Sagan 1967), which can be considered as a landmark of the endosymbiotic theory, was finally published in the *Journal of Theoretical Biology* after many rejections. Margulis was famous for her stubbornness defending her theory against the neodarwinists. The molecular demonstration that eukaryotic organelles, mitochondria and chloroplasts, were bacterial descendants proved that she was right and can be considered the first experimental evidence of the endosymbiogenesis theory.

She defended cooperation rather than competition between species as the most important evolutionary driver.

Being interested in the importance of gases as microbial metabolic substrates and products she met Lovelock and started a very productive collaboration. In 1974, they published a seminal paper describing the bases of the Gaia hypothesis.

Margulis was a prolific author of scientific papers and books, a science educator and very committed with science popularization. She received many awards throughout her career, and in 1983, she was elected member of the National Academy of Sciences.

Definition

Mars is the fourth ► [Planet](#) from the Sun and one of the terrestrial planets. It is named after the Roman god of war.

Overview

Mars accreted rapidly in a couple of million years (Brasser 2013) and differentiated within a few tens of millions years after the formation of the ► [Solar System](#) into a core, ► [mantle](#), and ► [crust](#), as indicated by isotope geochemistry (Lee and Halliday 1997; Mezger et al. 2013). It is commonly thought that the bulk composition of Mars is “chondritic” (Dreibus and Wänke 1985), i.e., similar to the composition of Carbonaceous Chondrites, the most primitive materials in the Solar System. The Fe-Ni-FeS core is dense and metal rich (Fig. 1) and its radius is about 50% of the surface radius, the exact value depending on

Mars, Fig. 1 Tentative cutaway view of the Martian interior. (From Stevenson 2001; reprinted with permission, © Nature Publishing Group)

its content of lighter elements like sulfur. The remnant magnetization of parts of the Martian crust indicates that core convection induced by energy from core cooling and/or inner core growth might have produced a core magnetic dynamo and a global [magnetic field](#) (Stevenson 2001). Evidence for crustal magnetization is mainly found in very old terrain and is absent in the largest impact basins, so the dynamo likely ceased before their formation about 4 Ga ago (Acuna et al. 1999) although this conclusion has been challenged (Schubert et al. 2000). For a discussion of the Martian dynamo see Connerney et al. (2004).

The dynamic range of geopotential topography (i.e., the topography after subtraction of the gravitational potential or *areoid* from planetary radii) on Mars is 29.5 km, the largest of all terrestrial planets (Fig. 2). The major features – the lowest and highest elevations – are represented by deep impact basins and large shield volcanoes, respectively. The lowest single point of the Martian surface is located in Hellas Planitia (−8180 m below the Martian datum) and the highest point is the summit of Olympus Mons (+21,300 m). The current thick elastic lithosphere of Mars allows maintaining such huge surface loads (e.g., Smith

et al. 2001). The surface shows a global dichotomy or asymmetry in topography as well as in morphology (Watters et al. 2007). The southern hemisphere (about two third of the planet) displays significantly higher elevations and a rougher morphology, dominated by heavily cratered terrain. The border between the two hemispheres is in large parts marked by a topographic scarp with heights of up to several kilometers. An overview of basic facts about Mars is given in Tables 1 and 2.

Crust and Mantle

The Martian crust has a mean thickness between 30 and 80 km (perhaps up to 100 km), as inferred from gravity and topography (e.g., Zuber et al. 2000; Neumann et al. 2004). It is thicker in the southern highlands and thinner in the northern lowlands. The bulk composition of the Martian crust is assumed to be basaltic (Fig. 3), although minor amounts of alteration products have been identified (overviews on surface composition are given in Bell 2008). Thermochemical evolution models (reviewed by Breuer and Moore 2007) suggest that most of the crust was produced during the first billion years. According to the widely accepted compositional model of Wänke and

Mars, Fig. 2 Topography of Mars (shaded and color-coded elevation model derived from the Mars Orbiter Laser Altimeter (MOLA) data; Mollweide projection)

Dreibus (1994), the silicate mantle of Mars is Fe-rich and contains radiogenic elements in terrestrial abundances. Converting this composition to a pressure-dependent mineralogy, Longhi et al. (1992) obtain a layered mantle structure with an olivine-rich upper part, a transition zone of silicate spinel, and a lower part consisting mainly of perovskite (see Sohl and Schubert 2007, for a discussion of interior structure models). The thickness of the elastic lithosphere is variable over space and time and it is currently up to three or four times thicker at the North Pole (>300 km) than at the Tharsis volcanoes (Grott and Breuer 2010). The average surface heat flow estimated from the elastic lithosphere thickness variation over time decreased from higher values in the ► **Noachian** ($\sim 50\text{--}100 \text{ mW m}^{-2}$) to current values of the order of $\sim 10\text{--}20 \text{ mW m}^{-2}$ (Grott et al. 2013).

Global Geology

The geologic surface record of Mars spans more than four billion years (Ga). Following the accepted stratigraphic system for Mars, this time is subdivided into the Noachian ($\sim 4.1 \text{ Ga}$ to

$\sim 3.6 \text{ Ga}$), the ► **Hesperian** ($\sim 3.6 \text{ Ga}$ to $\sim 3 \text{ Ga}$), and the ► **Amazonian** ($\sim 3 \text{ Ga}$ to present) periods (Tanaka and Hartmann 2008). The precise boundaries between the periods depend on the cratering model that is used to derive absolute ages from crater size frequency distributions (Hartmann and Neukum 2001). The pre-Noachian is not represented by surface outcrops. More than 40% of the surface is Noachian in age (Fig. 4), as well as the largest well-preserved impact basins Hellas, Argire, and Isidis (Solomon et al. 2005). Noachian rocks are primarily found in the southern highlands, whereas Hesperian surfaces are more widely scattered. Large portions of the ancient crust in the northern lowlands are overlain by a relatively thin Hesperian cover of volcanic and sedimentary materials. Amazonian rocks are concentrated in volcanic regions (see below). The geologic surface inventory of Mars is very diverse and reflects the action of both endogenic and exogenic processes (Carr 2006).

Volcanism and Tectonics

Evidence for volcanism on Mars is abundant (Greeley and Spudis 1981). About 15 huge

volcanic shields, including the largest volcano in the Solar System, ► [Olympus Mons](#), as well as hundreds of smaller edifices and spatially extensive volcanic plains attest to the significant magmatic activity of Mars. Volcanism was active over all of Mars’ history, but the intensity has decreased over time. After the Noachian, volcanic resurfacing mainly focused on the two largest volcanic provinces of the planet, ► [Tharsis](#) and Elysium (Fig. 4). Volcanic eruption products are mainly basaltic, based on the analogy to terrestrial basaltic landforms, the analysis of ► [SNC Meteorites](#), the in situ investigation of rocks and soils by landed missions, and spectral measurements from orbit (Fig. 3) (e.g., Grott et al. 2013). The Martian environment, in particular the low atmospheric pressure, leads to different eruption conditions as compared to Earth (Wilson and Head

1994). Since magma contains volatiles, volcanism has released large amounts of water and other volatile species (e.g., CO₂) into the Martian atmosphere (outgassing). The rates, timing, and total amount of outgassing are poorly constrained.

Mars, like the Moon or ► [Mercury](#), is a one-plate planet. There is no morphological surface record of plate tectonics. However, a very early phase of plate tectonics could help explain the

Mars, Fig. 3 Composition of Martian surface materials shown in a diagram of total alkalis (vertical axis) versus silica. M

dynamo activity and would have avoided early massive melting on Mars. Its morphological traces might have been overprinted by later resurfacing processes.

The single largest tectonic feature on Mars is the global dichotomy, which separates the southern highlands from the northern lowlands. The origin of this global dichotomy remains unknown, despite attempts to explain it as a consequence of an early Magma Ocean, mantle convection, an early phase of plate tectonics, or an exogenic process involving one or more impacts (Solomon et al. 2005). It was long thought that the southern highlands are much older than the northern lowlands, because much fewer craters were visible on images of the latter. Highly accurate topographic data from laser altimetry showed a large population of craters in the northern lowlands that have a very subdued topographic expression, obscuring their visibility in imaging data. If these craters are taken into account, the bulk of the crust in the northern lowlands seems to

be as old as in the southern highlands (Frey et al. 2002).

Except for the dichotomy, the Tharsis rise in the western hemisphere and, less importantly, the formation of Isidis Planitia and the Elysium rise in the eastern hemisphere clearly dominate the tectonic map of Mars on a global scale (Banerdt et al. 1992). Tharsis, the key to the tectonic evolution of Mars, is often considered to be the possible expression of a hot spot or mantle plume. (For an alternative view, see Schumacher and Breuer 2007). Deformation modeling indicates that large-scale lithospheric (magmatic) loading over Tharsis, which is large relative to the radius of the planet, is dominated by membrane stresses, and generates concentric extensional stresses around the periphery and radial compressional stresses closer to the center of Tharsis, which were accommodated by the formation of radial grabens and rifts and concentric wrinkle ridges (Golombek and Phillips 2010). As for the volcanism, tectonic activity on Mars seems to have

Mars, Fig. 4 Simplified global geology of Mars. The three major physiographic features are the southern highlands, the northern lowlands, and the volcanic provinces of

Tharsis and Elysium (From Nimmo and Tanaka 2005). Unit age abbreviations: *N* Noachian, *H* Hesperian, *A* Amazonian, *E* Early, *L* Late

peaked early and has gradually waned with time, although punctuated by episodes of higher and lower intensity. In general, vertical deformation is dominant and seems to be mainly associated with impact basins and large volcanic provinces.

Exogenic Surface Features

Impact craters are found on virtually every surface on Mars. Of particular interest are craters with unique morphologies that reveal the distribution of water or ice at the surface or in the subsurface (Martian crater morphologies are reviewed by Barlow 2010). Rampart craters (Fig. 5c) are only observed on Mars. It is thought that they penetrated the ground down to an ice- or water-rich layer. The minimum (or onset) diameter of rampart craters, therefore, can be used to determine the maximum depth of the ice or water table at the time of the impact. Other impacts might have strengthened (armored) an ice-rich target against erosion (e.g., by covering the ice by ejecta and protecting it from sublimation), so the present crater and its ejecta are

elevated with respect to their surroundings (“pedestal” craters). Wind-blown materials (sand and dust) are also widespread and can be observed on almost any high-resolution image, where they build aeolian bedforms such as ripples and different types of dunes. Wind was (and most probably still is) also an erosional force, and can be considered to be the most active geological agent on present-day Mars (Greeley and Iverson 1985). ► [Valley Networks](#) (Fig. 5a) and ► [outflow channels](#) (Fig. 5e) resemble erosional patterns carved by water and are discussed below. Many young (Amazonian) landforms on Mars that were probably formed by exogenic processes show a latitude-dependent geographic distribution. They include surface mantling, lobate debris aprons, lineated valley fill and concentric crater fill, viscous flow features, ► [gullies](#), and patterned ground. Collectively, these landforms (many of which are morphologically analogous to glacial and periglacial landforms on Earth) are hypothesized to represent the surface records of Martian ice ages (Head et al. 2003) that were induced by

astronomical forcing and associated climate changes (see below).

Atmosphere and Present-Day Climate

The Martian atmosphere is primarily composed of CO₂ (95%) with a little nitrogen, argon, and oxygen (Table 3). The atmospheric pressure at the surface ranges from 1 to 14 mbar depending on location and season (compared to 1013 mbar on average at sea level on Earth). In spite of these differences, the Martian climate system is similar to the Earth climate system in many aspects. The two planets rotate with almost the same rate and a similar obliquity. The length of day is thus almost the same (24 h and 40 min on Mars) and the seasonal cycle is comparable. In such conditions, the general circulation is controlled by similar processes (Read and Lewis 2004): On both planets, the Hadley circulation (the process that generates the trade winds) is important at low latitudes, whereas “baroclinic” planetary waves (a succession of low- and high-pressure zones) dominate the weather system at midlatitudes. However, with such a thin atmosphere and a dry soil, diurnal and seasonal surface temperature variations are much more marked, with temperatures typically ranging between 20 °C and –135 °C). Briefly, the climate of Mars is “hyper-continental.” To first order, the Martian meteorology can thus be compared with what one would expect on a cold, dry desert-like Earth. However, just like the climate system on the Earth is not controlled only by temperature gradients and the atmospheric circulation because of the presence of oceans and water clouds, several phenomena make the climate system more complex on Mars.

Mars, Table 3 Principal constituents of the atmospheres of Mars (volume mixing ratios), compared to the Earth

Gas	Symbol	Mars (%)	Earth (%)
Carbon dioxide	CO ₂	95.32	0.035
(Molecular) nitrogen	N ₂	2.7	78
Argon	Ar	1.6	0.93
(Molecular) oxygen	O ₂	0.13	20.6
Carbon monoxide	CO	0.07	0.00002
Water	H ₂ O	~0.03	~0.4

Firstly, as much as 30% of the ► carbon dioxide atmosphere condenses every winter at high latitudes to form polar caps, inducing surface pressure variations all over the planet (CO₂ cycle). Secondly, a highly variable amount of suspended dust modifies the radiative properties of the atmosphere, with global dust storms sometimes totally shrouding the planet (dust cycle). Finally, a peculiar hydrological cycle occurs on Mars, with water vapor transported by the atmosphere and the formation of clouds, hazes, and frost (water cycle).

Water on Mars Today

Water is almost everywhere on present-day Mars, in solid or gaseous state (Carr 1996). There are several known types of reservoirs:

First, relatively pure, white ice is directly exposed at the surface of Mars in an area of about 1000 km in diameter around the north pole. The thickness of this ice layer may vary from a few millimeters at its boundary up to a few meters or a few tens of meters in some locations near its center.

This ice layer is in direct interaction with the atmosphere, and is the principal surface reservoir involved in the atmospheric water cycle: in summer, the ice is warmed by the sun and sublimates. For a few weeks, the northern polar region becomes a source of water vapor that is transported away within the atmosphere. During the rest of the year, most of this water ultimately comes back to the northern polar cap through various transport mechanisms. The cycle is closed and near equilibrium. The amount of water involved in the seasonal water cycle is small. If one could precipitate the water content of the atmosphere on the surface, a layer thinner than a few tens of micrometers would be obtained even in the “wettest” regions. In the cold Martian conditions, though, saturation is often reached. Therefore, clouds form in the atmosphere and frost can condense onto the surface. The atmospheric water vapor should also be able to diffuse into the porous subsurface.

The surface ice near the northern pole appears to cover a much bigger structure made of thousands of layers of ice and dust that have

accumulated over more than 3000 m in thickness (see Clifford et al. 2000). These northern polar layered deposits are thought to be comparatively young, preserving a record of the seasonal and climatic cycling of atmospheric CO₂, H₂O, and dust over the past million years.

Radar observations of the south polar region demonstrated that the thick southern polar layered deposits (about 1000 km in diameter, and 2-km thick) accumulated around the pole are also composed of relatively pure water ice (Plaut et al. 2007), currently isolated from the atmosphere by a layer of dry sediments in most locations.

Near the south pole, the small (300 km), white, bright residual cap is primarily composed of carbon dioxide ice, and for a long time it had been assumed that no water ice layer was present at the surface in the southern polar region. Observations of the imaging spectrometer OMEGA (Observatoire pour la Minéralogie, l' Eau, les Glaces, et l' Activité) aboard ► [Mars Express](#), however, revealed the presence of perennial water ice deposits at the edges of the CO₂ ice bright cap, and even in large areas tens of kilometers away from it. Most likely, the permanent CO₂ ice cap lies on an extended water ice layer (Bibring et al. 2004).

In both the northern and southern hemisphere, poleward of about 55–60° latitude, the Mars Odyssey Gamma-Ray Spectrometer investigation

has shown that where ice is not exposed at the surface, it is still present just beneath the surface (below an ice-free layer a few centimeters thick), typically in the form of a dirty ice layer more than 1-m thick and with no less than 50% of ice. Moreover, in these areas the unique morphology of the ground is consistent with the presence of a few meters thick ice layer coating the surface (see a synthesis in Head et al. 2003). In 2008, the NASA Phoenix mission landed near 69°N in order to confirm the presence of ice and better understand its origin and its environment. As expected, a layer of ice was found just a few centimeters below the surface (Fig. 6).

In specific locations in midlatitudes and even in the tropics, there is geomorphologic and radar sounding evidence of buried ice landforms that are reminiscent of the debris-covered glaciers that can be found on Earth. The ice is thought to have been transported in the atmosphere, deposited, and then insulated and protected by a layer of sediments. The origins of these deposits could be related to climate changes due to time variations of orbital parameters (see below).

Below these buried ice layers, and even at lower Martian latitudes, it is likely that the large pore volume of the Martian subsurface regolith might be partly filled by ice. Calculations of the thermodynamic stability of ground ice suggest

M

Mars, Fig. 6 An image of the Martian surface beneath NASA's Phoenix Mars Lander taken by Phoenix's Robotic Arm Camera (RAC) on the eighth Martian day of the mission on June 2, 2008. A superficial dust layer, shown in the dark foreground, has been blown off by Phoenix's

thruster engines, exhibiting an ice-rich layer a few centimeters below the surface. The presence of the ice in Mars high latitudes had been remotely detected by the Mars Odyssey Gamma-Ray Spectrometer investigation in 2002. (Image: NASA/JPL)

that it can exist very close to the surface at high latitudes, but can persist only at substantial depth (several hundred meters) near the equator (Squyres et al. 1992). Observational evidence of the subsurface ice might be the presence of impact craters with distinctive lobate ejecta (*rampart craters*; Fig. 5c) that are not found on the Moon, and that apparently owe their morphology to the melting and vaporizing of ground ice during the impact. The size frequency distribution of these craters is consistent with the depth distribution of ice inferred from stability calculations. Small, fresh impact craters in mid-latitudes have excavated water ice and hence unambiguously demonstrate that water ice is present in the very shallow subsurface (Byrne et al. 2009).

Liquid Water on Mars Today

To form liquid water, H₂O must be exposed to a pressure above 6.1 mbar and a temperature above the freezing point (0 °C for pure water), and below the boiling point (which depends on pressure). Such conditions are not uncommon at the surface of Mars, for instance in the lower plains in summer in early afternoon. They last only a few hours at most, however, and only the first few millimeters below the surface can be heated above 0 °C. Because of the low vapor pressure of water in the atmosphere, any ice that may be present at the surface (in the morning, for instance) sublimates into the atmosphere well before it can melt (e.g., Haberle et al. 2001). The existence of liquid water in a “metastable” state in some specific circumstances has been suggested, but remains unlikely. In some cases, dissolved salts could form a brine, which can be liquid at temperatures well below the freezing point of pure water (Fairén et al. 2009).

Liquid water may exist in the subsurface, more likely at several thousands of meters below the surface, where water present in the pore space could be heated by the geothermal flux (Squyres et al. 1992). The most “optimistic” scientists imagine that liquid water aquifers could exist at much shallower depth, up to a few tens of meters below the surface, as a consequence of local geothermal activities, but, again, this remains speculative. In particular, radar soundings have not yet been able

to detect any liquid water aquifers, in spite of the fact that the liquid water dielectric properties should make it detectable in theory.

Climate Changes Due to Obliquity and Orbital Parameters Variations

As on Earth, the climate on Mars depends on the planet’s orbital and rotational parameters, and in particular its obliquity (inclination of Mars’ axis of rotation with respect to its orbit plane). For Earth, such oscillations are small ($\pm 1.3^\circ$ for the obliquity), but they are thought to have played a key role in the glacial and interglacial climate cycles. For the case of Mars, calculations have shown that Mars’ obliquity varied widely and somewhat erratically in the past, between 0° and more than 60° (the current obliquity is 25.2°) (Laskar et al. 2004). These variations must have had a strong impact on the Martian climate. A quantified description of these past climates is not easy because one has to predict the response of a complex system that includes the atmospheric circulation and the coupled CO₂, dust, and water cycles. Nevertheless, on the basis of theoretical considerations and with the help of numerical climate simulations, we can speculate about the major changes.

During periods of low obliquity, with an obliquity below 20°, the seasonal cycle is weaker than today. The latitudinal extension of the seasonal polar caps is reduced. The polar regions experience a net decrease in solar heating (the sun is lower on the horizon) and thus a net cooling. It is likely that the mass of frozen atmosphere trapped at the poles (currently near the southern pole) increases at the expense of the total atmospheric mass. Models also show that in such conditions the water and dust cycle are much less active. The atmosphere is thinner and clearer. Mars is then a frozen world.

During periods of high obliquity. Beyond 30° of obliquity, the seasonal cycle is stronger than today. For instance, the CO₂ ice seasonal polar caps extend to the tropics in winter when the obliquity reaches 40°. In the polar regions, the increase of annual mean insolation leads to a warming of the relatively deep subsurface. In summer, the polar water ice reservoir is strongly

heated and releases tens to hundred times more water than today, inducing a very active hydrological cycle (vapor, clouds, frost). Beyond obliquities of 35–45°, computer simulations of the Martian climate suggest that warming of any ice left at the poles would liberate such a large amount of water into the atmosphere that, in certain areas, water vapor would condense and precipitate out much more readily than it could sublime. In these areas, ice would therefore have accumulated (as long as there was still a source at the pole) and might even have formed glaciers (Forget et al. 2006). The remains of these glaciers (moraines) and possibly debris-covered glaciers have indeed been found where the models indicate they once existed. Today, it seems that a large amount of the ice that may have been transported in and out of the polar regions is back at the poles. If this scenario is confirmed, the polar layered deposits can probably be attributed to the past oscillations of the climate.

Evidence for Transient Liquid Water on Mars in the Recent History: Outflow Channels, Gullies and Recurrent Slope Lineae

Three types of very different geological landforms suggest that liquid water may occasionally flow briefly on Mars in the relatively recent geological past (Baker 2001).

Outflow channels (Fig. 5e) are immense and deep channels that appear to have been carved by flowing water, mud, or glaciers (Baker 1982). Their widths can exceed 100 km, and they can reach lengths of >1000 km. Most are several billions years old, but seem to have been episodically active in several stages, and some outflow channels appear to be less than a few tens of millions of years old. Outflow channels show a peculiar morphology: they have no tributaries, and their geographical origin is quite localized. On their floors, large numbers of channels sweep around prominent obstacles such as impact craters, sculpting teardrop-shaped structures tapering in the direction of the flow. The geometry of these streamlined “islands” has led researchers to conclude that they were shaped by very turbulent liquid water, rather than by ice, lava or mud, and that only sudden, short-lived bursts of vast

amounts of water can explain the characteristics of the outflow channels. The water could have been suddenly liberated from a pressurized underground water reservoir, trapped beneath the Martian ► [cryosphere](#) (Lasue et al. 2013). The formation of the outflow channels does not require the climate to have been very different from what is observed today.

► *Gullies* (Fig. 5d) are hundreds of meters to kilometer-long structures usually found on steep slopes with an apron or fan of debris at the distal end. They seem to have been created by flowing water in geologically recent times: perhaps a few million years ago, perhaps much more recently. Since their discovery in high-resolution images (Malin and Edgett 2000a), their origin is debated. Some researchers put forward the idea that there are aquifers below ground, warmed by energy from within Mars. These could flow at the surface intermittently. However, this scenario does not satisfactorily explain the distribution of the flow features: they seem unconnected with any volcanism. Neither does it address the fact that these features are observed on isolated peaks and even on dunes, where groundwater is not expected. An alternative scenario would be simply to assume that they were formed when ice or snow deposited during period of high obliquity (see above) may have briefly melted, inducing debris flows and gullies.

Recurrent Slope Lineae are albedo markings that recurrently appear and disappear in seasonal cycles on relatively steep, equator-facing slopes in the southern mid-latitudes during summer (McEwen et al. 2011). They resemble water tracks propagating downslope, although there is probably no water directly exposed at the surface. More likely, water may seep through the very shallow subsurface and wettens the overlying regolith, making it appear darker. The source of this hypothesized water, which may occur in the form of brines with a depressed freezing temperature, is unknown.

Early Mars: A Potential Habitable Planet More Than 3.5 Billion Years Ago

About half of the surface of Mars is extremely ancient, dating back from prior to 3.8 billion years

ago, a time when the impact rate from infalling meteoroids and planetesimals was much higher than today. This part of the Martian surface, mostly in the southern highlands, has also kept the record of a period where the environment was much different from what it became afterward. There is evidence that, at this time, liquid water was present on the surface of Mars and could have formed rivers, lakes, and possibly an ocean.

- *Valley networks* (Fig. 5a). Valleys, with characteristics very similar to terrestrial river drainage valleys, were discovered in 1971 by the Mariner 9 orbiter. Smaller valleys coalesce downhill into larger valleys, forming a dendritic network. These valleys are observed on most of the surfaces older than 3.5–3.8 billion years (Carr 1996), but only very few have been identified on more recent terrain. This finding suggests that Mars enjoyed an environment suitable for the formation of these valleys more than ~3.5 billion years ago (at least periodically), but that such conditions rarely occurred later. The recent exploration era is revealing more and more valley morphologies that suggest that precipitation and runoff was involved, perhaps generated by snow melt.
- *Lacustrine deposits?* (Fig. 5b and f). High-resolution images provided new evidence of deposits, mostly within craters, that have an appearance similar to layered lacustrine deposits, deltas, sedimentary terraces, and shorelines (Malin and Edgett 2000b, 2003; Kleinhans 2010). Well-defined layering has been identified within these deposits, supporting the idea of standing water, although windblown or airfall sediments could account for some of the observations.
- *An ancient ocean?* Most outflow channels seem to end downstream in the northern lowlands, which would have acted as a huge sink for water and sediments. If the Noachian were warm enough to prevent the formation of a sufficiently thick ► [cryosphere](#), which could trap pressurized groundwater beneath and maintain an elevated global water table, the formation of a primordial ocean in the lowest part of the global topography (e.g., Hellas, northern lowlands) would seem plausible, if not inevitable (Clifford and Parker 2001). According to this model, such an ocean would have frozen with time, and finally the water would have been assimilated in the crust in a thickening cryosphere. It has to be noted, however, that there is no unambiguous morphologic or mineralogic evidence for an ancient ocean on Mars, and its existence is still contentious.
- *Erosion rate:* A detailed analysis of the ancient terrains reveals that old impact craters larger than about 15 km in diameter have a substantially degraded appearance. Crater rims, ejecta blankets, and central peaks have been removed in many cases and the crater interiors have been filled in with debris. Craters smaller than about 15 km have been erased entirely. However, craters formed in regions a few hundreds of millions years younger are much better preserved. This observation suggests that in the distant past, before 3.8 billion years ago, the erosion rate was orders of magnitude more efficient than later in the history of Mars (Jakosky and Phillips 2001). While this erosion could have many possible causes, it is generally thought that liquid water was the eroding agent.
- *Mineralogy:* On Earth, the composition of many rocks and soils points to their formation in the presence of liquid water (e.g., hydrated materials). On Mars, such evidence is rarer. The observations gathered by the thermal infrared spectrometer TES (Thermal Emission Spectrometer) aboard Mars Global Surveyor and by the near infrared imaging spectrometers OMEGA and CRISM (Compact Reconnaissance Imaging Spectrometer for Mars) aboard Mars Reconnaissance Orbiter suggest that most surfaces are either of volcanic origin, or covered by dust (Christensen et al. 2001; Bibring et al. 2005). However, in 1998, TES revealed the presence of three regions with an exposed surface enriched in the iron oxide mineral ► [hematite](#), a weathering product inferred to have been precipitated from water flowing through the crust. One of these regions, Sinus Meridiani, was selected to be

explored by Opportunity, one of the two Mars Exploration Rovers that began their mission in January 2004. Opportunity did confirm the presence of hematite, and made an even more interesting discovery: it detected the presence of the sulfate salts jarosite ($\text{KFe}_3^{(\text{III})}(\text{SO}_4)_2(\text{OH})_6$) and magnesium sulfates like kieserite ($\text{MgSO}_4 \cdot \text{H}_2\text{O}$) in the sedimentary outcrops of the area, with physical characteristics indicative of aqueous transport (Squyres et al. 2004). On this basis, the Opportunity team concluded that these rocks probably record episodic inundation by shallow surface water, evaporation, and desiccation. At the same time, OMEGA actually discovered and mapped hydrated sulfates – kieserite, polyhydrated sulfates, and even gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) – mostly in light-toned layered terrains located in Terra Meridiani, ► [Valles Marineris](#), and Margaritifer Sinus. Even more interestingly, the OMEGA team discovered clays (phyllosilicates, primarily iron/magnesium smectites) in several locations restricted to the most ancient terrains (Poulet et al. 2005), suggesting that clay formation may have taken place primarily during the earliest portion of Martian history. Clays were probably formed by the action of liquid water on volcanic rocks such as ► [basalt](#), over tens of thousands of years. Altogether, the mineralogical investigations suggest that Mars experienced, early on, a period when liquid water was probably abundant, and able to soak soils during episodes long enough for clays to form. Later, in a drier and more acidic environment, sulfate salts were more likely to form (Bibring et al. 2006). The fact that some alteration minerals can still be observed at present, although they formed several billion years ago and are easily transformed into other materials by, e.g., ► [diagenesis](#), suggests that water was very limited on the Martian surface from soon after their formation until today (Tosca and Knoll 2009).

The Early Mars Climate enigma. The possible existence of relatively warm conditions suitable for surface liquid water on Mars 3.8 billion years

ago is unexpected. Most experts believe that at that time, the young sun was less intense than today and its luminosity 25% lower than at the present time. Since Mars is about 1.5 times more distant from the sun than the Earth, the solar energy available on Mars then was only one third of what we enjoy on Earth today. In such conditions, the radiative equilibrium temperature (► [effective temperature](#)) of the planet should have been -75°C , not taking into account the atmosphere. In such conditions, what could have made the climate so warm and wet?

- *Atmospheric greenhouse effect:* The composition of the early Mars atmosphere is not well constrained, but it was probably mostly composed of carbon dioxide with a surface pressure between a few hundreds of millibars to a few bars. Such amounts are consistent with the initial volatile inventory of a planet like Mars, and it is likely that large amounts of CO_2 and H_2O should have been released in the atmosphere by the substantial volcanism that occurred on early Mars, associated with the formation of the volcanic plains and the Tharsis bulge. Both CO_2 and H_2O are greenhouse gases (► [greenhouse effect](#)), but their ability to warm the planet through greenhouse effects is limited, and they may not have been able to solve the early Mars climate enigma by themselves (see review in Haberle 1998). Other greenhouse gases, such as NH_3 , CH_4 , or SO_2 have been proposed to help solve the enigma, but they should have been photochemically unstable in the early Mars atmosphere and rapidly exhausted, unless produced by a surface or subsurface source (volcanism? life?). However, the presence of sulfate salts on Mars has motivated recent studies involving SO_2 in the atmosphere. Another possibility is that Mars was warmed by CO_2 ice clouds. These clouds tend to form in a thick CO_2 atmosphere. Models show that they can reflect a significant part of the thermal infrared radiation emitted by the surface and warm the planet through an exotic “scattering greenhouse effect” (Forget and Pierrehumbert 1997). An unsolved problem with CO_2 -supported

greenhouse scenarios involving a thick ($\gg 1$ bar) atmosphere is that it is not easy to explain the loss of this atmosphere into space with known escape processes. If there was indeed a thick CO_2 atmosphere on early Mars, much of it should be stored as carbonates in subsurface reservoirs (Lammer et al. 2013).

- *Role of geothermal flux.* Some geological evidence related to liquid water on early Mars could be explained by the early large geothermal heat flux (estimated to be 5–10 times the present-time values on average) that contributed to warm the near subsurface and probably induced intense geothermal activity. Volcanic intrusions may have locally caused even larger heat flow values.
- *Asteroid impacts.* Large impacts during the heavy bombardment may have warmed the climate episodically by generating a transient steam atmosphere. The water vapor in this steam atmosphere may have acted as greenhouse gas, and rain may have been generated (review by Toon et al. 2010).

Life on Early Mars?

Life was probably present on Earth when Mars enjoyed habitable conditions more than 3.8 billion years ago. If life on Earth arose as a result of fundamental and repeatable physicochemical processes, there is no a priori reason why life might not also have emerged on the Red Planet, more than 3.5–4 billion years ago. The study of Mars shows that conditions at its surface were such that widespread liquid water could have been present there for a limited period only – most likely during the first ~ 1 billion years of Martian history. On Earth, the first multicellular organisms (and, a fortiori, the first animals and plants) appeared after more than 2 billion years of unicellular predecessors. If any life form evolved on Mars, this suggests that it was probably primitive. However, it is not clear if such a long evolution time is required for genetic evolution, or because physical and chemical conditions on Earth (e.g., amounts of oxygen) were incompatible with the existence of more complex creatures? Perhaps evolution did not proceed in the same way on Mars, and some optimistic scientists have

speculated that more evolved forms of life could have existed on Mars at the same epoch.

Life on Mars Today?

Mars today is cold and dry. If one assumes that Martian life requires the same necessary ingredients as life as we know it on Earth (Jakosky et al. 2007), the primary challenge for potential Martian organisms would be the access to liquid water. This is especially true at the surface or near the surface. Moreover, the Martian surface is exposed to intense [▶ ultraviolet radiation](#), which should be lethal for most living organisms although there are microorganisms that have been reported to survive high radiation doses. Also, the upper few meters of the soil seem to have been sterilized by highly oxidizing compounds. In such conditions, assuming that life ever did get started on Mars, how could it have survived until today? If life has survived until the present day on Mars, we will have to look for it in those niches where liquid water may still be present. One possibility is several kilometers underground, where the planet's internal heat source ensures that temperatures remain above 0°C . “Interstitial” water could harbor life, as observed in deep Earth crust samples. Nearer to the surface, Martian volcanism, which, though on the decline, still might occur (Hauber et al. 2011), probably creates warmer places. Just as on Earth, organisms might exploit the relatively rich chemical resources found in such locations. It must be stated, however, that for life to have held out this long on the planet, Martian organisms would have needed a stable environment in their “bio-niches” for billions of years.

The detection of life on the Martian surface was one of the main objectives of the [▶ Viking](#) Landers (1976). An articulated arm, capable of digging into the surface, gathered samples of Martian soil. The samples were subjected to three investigations: the Pyrolytic Release, Gas Exchange, and Labeled Release experiments, which yielded negative or ambiguous results. However, the official verdict was finally negative (Klein et al. 1992), because the gas chromatograph coupled with a mass spectrometer, capable of detecting organic molecules at a concentration below one part per billion, found nothing.

An alternative way to detect biological activity on Mars is to monitor the presence of gases possibly produced by biological activity and which could not be present at a given level without the presence of life, like molecular oxygen on the Earth. There is no such obvious biogenic gas on Mars. However, the reported discovery of ► [methane](#) since 2004 from Earth-based and orbital observations has reactivated this investigation. Methane should be unstable in the Martian atmosphere, so its presence requires the existence of a source. In theory, this source could be unrelated to life. For instance, some methane on Earth is produced by hydrothermal activity, which leads to the oxydoreduction reaction between iron-bearing primary silicates (olivine and pyroxene) and water to form hydrogen and Fe(III)-bearing phyllosilicates, a process called ► [serpentinization](#). The hydrogen can then be used to produce methane by biologic and non-biologic mechanisms. However, the intensity of the source of methane inferred from the observations (local bursts of methane have been reported) is such that it would be comparable to the production of methane by serpentinization along the entire Mid-Atlantic Ridge on Earth (50,000–130,000 t/year). On a ► [planet](#) where the volcanic activity appears to be low at present, this would be unexpected. Because most of the methane produced on Earth is biogenic, it is thus tempting to speculate on a possible subsurface biological production. Nevertheless, the current environment on Mars would constitute a great challenge for life as we know it. The temperature and atmospheric pressure commonly prevent liquid water to be stable at the surface, which is also chemically harsh and affected by intense radiation. It is doubtful that organisms can survive today at the Martian surface (Knoll and Grotzinger 2006).

Future Directions

The exploration of Mars continues with the Mars Atmosphere and Volatile Evolution Mission (MAVEN), that was launched in November 2013. MAVEN will explore the planet's upper

atmosphere, ionosphere, and interactions with the sun and the solar wind. Scientists will use these data to determine the role that loss of volatile compounds, such as CO₂, NO₂, and H₂O, from the atmosphere to space has played through time, giving insight into the history of the Martian atmosphere and climate, liquid water, and planetary habitability. In 2016, an ESA orbiter with Russian contributions will search for trace gases such as methane, and will try to map their variations over time and location in the Martian atmosphere. The same orbiter will carry a demonstration lander. Also in 2016, NASA's InSight Mission will put a seismometer and a heat flow probe onto the surface of Mars. ESA's ExoMars rover (current launch date: 2018) will have the capability to drill 2 m into the ground to search for traces of life. NASA plans to send a rover to Mars in 2020 that searches for biosignatures and stores a diverse set of samples in a cache for potential return to Earth at a later stage. In the more distant future, the actual return of samples from Mars to Earth (► [Mars Sample Return Mission](#)) would be the most important step in Mars Exploration.

Mars 2020

Michel Viso
Innovaxiom, Paris, CX, France

Definition

Mars 2020 was designed on the technical heritage of → Curiosity (launched November 26, 2011; landed on Mars August 6, 2012) but aims to answer new science and technological questions and prepare a future return of Martian samples. The major components of this Mars 2020 mission are the cruise stage, the aeroshell composed of the front heat shield and the back shell. This aeroshell hosts descent stage which performed the Skycrane, lowering smoothly → Perseverance onto the Martian surface.

The Mission Mars 2020 was launched July 30, 2020, from Cape Canaveral (Florida USA). After around 6 month and a half of cruise, Perseverance successfully landed in Jezero crater February 18, 2021 (Fig. 1).

Mars 2020, Fig. 1 The illustration, almost the last terrestrial view of the descent stage, displays the actual components of the mission from top to bottom: the cruise stage, the back shell, intricately together the Skycrane and the rover Perseverance, the black box protecting the helicopter → Ingenuity attached under the belly of the rover and the front heat shield. Definition

Mars analogue sites are places on Earth that present one or more geological or environmental features similar to those found on Mars, either current or past.

History

Studies of ► [Mars analogue](#) sites have been an integral part of comparative planetary science, space exploration, and astrobiology for over a half-century (Léveillé 2010a). Following the successful Mariner missions of the 1960s, planetary scientists began studying in more detail Mars-like features and environments on Earth, including volcanic and erosional systems, glacial and thermokarst features, dunes, playas, and impact craters. Mars analogue sites were later studied in order to plan for possible landing sites for the Viking mission. Similarly, Mars analogue sites were used to test ► [NASA's](#) earliest life-detection instruments. Early microbiological studies of desert soils, including some from Antarctica and the Atacama, focused on the adaptations and survivability of microorganisms under Mars-like conditions. Since the Viking mission and more recent orbital and rover missions, new Mars analogue sites have been continually identified and studied as new data are returned to Earth and our understanding of Mars is deepened.

Overview

Mars analogue sites are defined as places on Earth that share one or more physical, chemical, or geological similarities with Martian ► [environments](#), either current or past (Farr 2004; Osinski et al. 2006; Léveillé 2009). Studies of analogue sites are an essential aspect of understanding remote or in situ robotic observations of Mars and to ultimately better understand our solar system (Chapman 2007). With respect to astrobiology, analogue sites provide insight into the limits to life on Earth, adaptations of organisms to extreme conditions, and the diversity and

distribution of habitable environments on Earth and possibly elsewhere in our Solar System (Rothschild and Mancinelli 2001; National Research Council 2007; Léveillé 2010b). Analogue sites are also indispensable to the study of the formation and preservation of microbial biosignatures, in both ancient and modern systems. Though no location on Earth is identical to any location on Mars, many terrestrial analogue sites do approximate conditions or features found on Mars. Extreme cold and dry conditions are perhaps the most important present-day Mars-like conditions that are especially relevant to astrobiology. Mars-like geological features on Earth include volcanic systems (including lava tubes), salt and sand dunes, gullies and canyons, polar and alpine deserts, and impact craters, as well as various hydrothermal and sedimentary systems (Farr 2004; Osinski et al. 2006; Chapman 2007; Léveillé 2009, 2010b).

Basic Methodology

The term fidelity is used to describe the similarity of an analogue site with respect to the extraterrestrial environment to which it is compared (e.g., Snook et al. 2007; Léveillé 2009). Analogue sites with multiple attributes that are closely related to Mars are said to offer a high fidelity. Several different analogue sites may be studied in order to fully understand the data generated during a space mission or to explain an extraterrestrial process. In studying Mars analogue sites, it is important to take into account what is similar and what is different to Mars and to ensure that differences do not affect the analysis for which the analogue site is used (National Research Council 2007).

With respect to astrobiology and ► [Mars](#), analogue sites can be used in at least three fundamental ways:

1. To better understand data returned from a Mars mission in order to assess the habitability potential of studied sites.
2. To predict and identify where past habitable environments may have existed on Mars.

3. To identify biosignatures (or biosignature suites) that may be searched for at a given location on Mars.

Results from such analogue studies can directly assist in the formulation of scientific objectives, as well as help to define operational and instrumentation requirements for future planetary missions.

Applications

Analogue sites have been used extensively to test hypotheses about possible extraterrestrial processes, including biosignature formation, degradation, and preservation. They can also be used to test exploration strategies, biosignature detection and measurement techniques, sample-handling protocols, and mission concepts in a variety of geological and environmental settings. Analogue sites can also be used to test and validate science instruments, robotic systems, and integrated hardware packages in challenging environments and under operating conditions representative of actual missions, at a relatively low cost and risk (Léveillé 2009).

Studies of analogue sites can also help to establish baseline abiotic signatures or provide positive controls for life-detection instruments. Similarly, issues of forward contamination and cross-contamination, as well as mitigation strategies and cleaning protocols, can be incorporated into many types of field-based studies at analogue sites.

Studies of analogue sites are also useful for the training of scientists and engineers (including remote science and engineering operations teams), mission planners, ground operation crews, and even astronauts, in a cost-effective, low-risk way (National Research Council 2007). By studying analogue sites, science teams can learn how to remotely detect and identify planetary features and perfect decisional protocols before missions begin (Chapman 2007). Field-based projects also help to train students in the tools and knowledge needed to participate in future astrobiology research, payload development, and ultimately missions. Some important examples of analogue sites for

astrobiology include the Haughton impact crater on ► [Devon Island](#) and the perennial springs of Axel Heiberg Island, Canada; the Antarctic Dry Valleys; the acidic river system of Rio Tinto, Spain; acidic lakes of Australia; and the ► [Atacama Desert](#), Chile. Other types of analogue sites showing promise with respect to astrobiology and Mars exploration include sites of active terrestrial serpentinization and exposed basaltic glass, lava tubes and caves, playa lakes, hydrothermal springs, as well as ► [permafrost](#) and ground-ice-containing areas.

Analogue missions refer to simulations of planetary surface missions that involve an integrated set of scientific and operational activities at an analogue site (Snook et al. 2007; Léveillé 2009). Analogue missions can specifically target operational requirements and produce lessons learned in order to reduce costs and risks associated with future missions. For example, analogue missions can help to develop and test sampling strategies and measurement requirements, make ground truth measurements, direct training in planning science operations, promote team building, and improve communications. Some examples of astrobiology-focused analogue missions include the MARTE drilling project at ► [Rio Tinto](#), Spain; the Life in the Atacama Desert project; and the AMASE project at Svalbard.

Future Directions

The US National Research Council has recommended that studies of analogue sites should be a fundamental component of Mars astrobiological research and the development of future robotic missions to Mars (National Research Council 2007). Testing Mars surface operations at analogue sites is also a high priority of the planetary science community (Farr 2004; Osinski et al. 2006). Integrated scientific and operational studies at analogue sites will likely be increasingly critical for Mars sample return missions, for which coordination of highly advanced technologies will be required at very carefully preselected sites (Borg et al. 2008). Analogue sites will also continue to be essential for

selecting landing and sampling sites, for sampling and site characterization strategies, and for planning overall mission operations, as well as for developing novel technologies for Mars missions. Increased international coordination and integrated field and remote operations teams will help to address future target mission requirements and scientific objectives.

Mars Analogues

Felipe Gomez

Centro de Astrobiología (CSIC/INTA), Instituto Nacional de Técnica Aeroespacial, Madrid, Spain

Definition

Extreme field sites on Earth that mimic some Mars condition are considered Mars analogues. Some Earth natural field sites are extreme due to very low pH, oxidant conditions, low temperature, or low water activity. Those extreme conditions characterize the Mars surface environment. Atacama dessert in Chile is one of the best recognized analogues for Mars surface due to the very low water activity and high UV radiation on the surface. Other interesting Mars analogue due to the low pH and associated geochemistry and mineralogy is the Spanish Rio Tinto. Jarosite is precipitated in the river bed resembling the chemistry associated to Meridiani Planum in the red planet.

Definition

The Mars Express mission is the first planetary mission of the European Space Agency (ESA). Decided in 1997, it was launched from Baïkonur on June 2, 2003, and was inserted into ► [Mars](#) orbit December 25, 2003, after proper maneuvers transferring the spacecraft into an elongated almost polar orbit. Mars Express started its orbital observations in early January 2004. The targeted duration of the mission was 1 Martian year (687 terrestrial days). However, the mission is still healthy and operating after more than 15 terrestrial years, and has been extended till the end of 2022, possibly till 2025. Some days before arriving at Mars, Mars Express ejected the Beagle 2 lander, designed to land and to perform surface measurements. Unfortunately, the contact with ► [Beagle 2](#) was lost and never recovered. However, the measurements and observations from orbit are making this mission one of the most successful for the exploration of Mars.

History

The Mars Express mission was conceived after the dramatic loss at launch of the Russian Mars 96 mission in November 1996. After being studied as a French then French/German “small mission,” embarking some spare models of instruments developed for Mars 96, it has been incorporated within the Horizon 2000 ESA science plan in 1997, as a “F-mission” (both Flexible and Fast), to be launched in 2003.

Overview

The 2003 launch opportunity was extremely favorable: a Soyuz rocket would be sufficient, and the overall cost could be capped at a very low level. To fit within the allocated mass of ~100 kg, five instruments were selected, out of the available spares developed for the Mars 96 mission: HRSC (High-Resolution Stereo Camera), built in Germany (G. Neukum, then R. Jauman, then R.T. Roatsch PI); OMEGA (Observatoire pour la Minéralogie, l'Eau, les Glaces et l'Activité, a visible and infrared hyperspectral imager), built in France, Italy, and Russia (J-P. Bibring, then J. Carter PI); SPICAM (Spectroscopy for Investigation of Characteristics of the Atmosphere of Mars, an ultraviolet and infrared atmospheric spectrometer), built primarily in France and Russia (J-L. Bertaux then F. Montmessin, PI); PFS (Planetary Fourier Spectrometer), primarily built in Italy (V. Formisano, then D. Grassi, then M. Giuranna, PI); and ASPERA (Analyzer of Space Plasmas and Energetic Atoms, an analyzer of ions and electrons in the outer atmosphere), primarily built in Sweden (R. Lundin, then S. Barabash, then M. Holmström, PI). ESA decided to add a lander (Beagle 2 was selected, C. Pillinger, PI) and an orbiter instrument to sound the subsurface: The selected one was named MARSIS (Mars Advanced Radar for Subsurface and Ionosphere Sounding, a subsurface and ionospheric radar sounder), built in cooperation between Italy and the USA (G. Picardi, then R. Orosei, PI). Finally, Mars Express would embark a Mars Radio Science Experiment (MaRS), with no specific hardware, using the radio signals to probe the planet atmosphere and surface (M. Pätzold, PI). With this suite of instruments, Mars Express is capable of sounding and analyzing, possibly in a coupled way, all Martian envelopes: its outer (ionized) atmosphere, its neutral atmosphere, its surface, and its subsurface, down to a few kilometers.

The variety and diversity of achievements is impressive. They cover all prime themes of Mars science, offering clues to decipher in an unprecedented fashion Mars' evolution at all timescales, from its seasonal changes to its climatic and

geological variations. It launched a profound revisiting of Mars properties and history.

Valles Marineris, seen by HRSC at an angle of 45 degrees to the surface in near-true color and with four times vertical exaggeration. The image covers an area of 630,000 sq. km with a ground resolution of 100 m per pixel. The digital terrain model was created from 20 individual HRSC orbits, and the color data were generated from 12 orbit swaths. The largest portion of the canyon, which spans right across the image, is known as Melas Chasma. Candor Chasma is the connecting trough immediately to the north, with the small trough Ophir Chasma beyond. Hebes Chasma can be seen in the far top left of the image.

Key Research Findings

Based on a list issued by ESA 10 years after launch, top ten scientific discoveries could be summarized as follows:

1. The ancient history of Mars has been fundamentally re-assessed after the detection by OMEGA of alteration minerals and phyllosilicates in particular. Hydrated phyllosilicates were formed, at a planetary scale, when long-standing bodies of water were present, either or both at the surface and subsurface levels: They record an ancient era of potential habitability. This happened during the first hundreds of millions years, while the dynamo was still active. OMEGA, then coupled to CRISM/MRO, have identified and located sites of astrobiological relevance, for future in situ and Mars Sample Return (MSR) missions.
2. Methane has been declared detected from orbit by the PFS spectrometer, with its spatial and vertical distribution mapped. Its presence would indicate that Mars is still either geologically or biologically active. It paved the way for further dedicated space investigations, with still controversial outcomes.
3. The HRSC has offered breathtaking 2D and stereoscopic views of the planet down a ~ 10 meters scale. It provides new insights into the planet's topography, allowing a much better understanding of the formation and evolution of the surface geological features in their diversity, at a global planetary scale. As examples, tropical and equatorial landforms have been identified, as well as possible glaciers active just a few thousand years ago: They likely trace the chaotic evolution of the planet obliquity.
4. The north and south polar layered deposits consist of nearly pure water ice, as deduced from the MARSIS radar data. Unique maps of H₂O ice and CO₂ ice in the polar regions have been produced by OMEGA: The CO₂ southern ices constitute a very thin veneer on top of a massive water ice glacier. Subsurface polar icy layers have also been tentatively identified by MARSIS.
5. The combination of digital terrain models with HRSC coverage at high resolution (better than 20 m/pixel) indicates very young ages for volcanic processes, which may have persisted until recent times, a few million years typically. They could still be active near the North Pole: Mars is just reaching its geological death.
6. The Analyzer of Space Plasma and Energetic Atoms (ASPERA) has found that the solar wind is slowly stripping off the high atmosphere down to 270-km altitude and has measured the current rate of atmospheric escape of planetary ion, which happens to be relatively low and occurs in bursts. The composition of the escaping plasma has been precisely measured.
7. SPICAM has enabled to build ozone and water vapor maps at a planetary scale, over all seasons, monitoring their respective

formation and evolution, essentially anti-correlated. Auroras have also been revealed by SPICAM, over midlatitude regions. They are produced by the precipitation of electrons, measured by ASPERA above regions with crustal paleomagnetic field. SPICAM has also detected airglows in the Martian nightside.

8. A transient ionospheric layer, due to meteors burning in the atmosphere, has been identified by radio occultation.
9. Phobos, the largest Mars moon (27 km large), has been intensively observed, by all instruments, during a few close flybys, down distances less than 100 km, never achieved before. It led to refined measures of its size, mass, density, interior and surface structure, and surface composition, with in particular no features associated with neither hydrated nor carbonaceous constituents.
10. Very-high-altitude (up to 80 km) mesospheric CO₂ ice clouds have been detected and characterized in the equatorial region of Mars. This discovery enlightens the processes responsible for the cloud formation at Mars and around Earth, as well as for the sustenance of surface liquid water during the early Mars history.

Although limited in cost and ambition, and started with the failure Beagle 2, the Mars Express mission has fundamentally contributed to the understanding of the processes which drove the evolution of Mars, all along its history.

It has launched ESA as a major actor of planetary space exploration.

[MGS](#)

Definition

Mars Global Surveyor was a ► [NASA](#) orbiter that mapped and monitored planet ► [Mars](#) with five scientific instruments between its arrival at Mars on September 11, 1997, and November 2006. Mars Global Surveyor was the first fully successful mission around Mars since the ► [Viking](#) missions in 1976. It revolutionized our understanding of the red planet and ushered in a new era of Mars exploration.

History

After the very successful Viking missions launched in 1976, it took more than 16 years for NASA to select, design, and launch a new orbital mission to Mars: Mars Observer. It carried an ambitious scientific payload with seven instruments. Unfortunately, contact was lost 3 days before orbit insertion on August 21, 1993, due to an unknown failure of the spacecraft. The smaller Mars Global Surveyor project was then initiated on the ashes of Mars Observer, with the objectives of using spare models or copies of five of its experiments.

Overview

Mars Global Surveyor (MGS) was a 1060 kg (full mass at launch) spacecraft launched on November

7, 1996 and inserted into Mars Orbit on September 11, 1997. By March 9, 1999, MGS had slowly circularized through aerobraking to a Sun-synchronous, near-polar orbit with an average altitude of 378 km, mapping Mars at solar local time close to 2 am–2 pm (Albee et al. 2001). It operated until a battery failure in November 2007.

Its payload included five instruments that revolutionized our understanding of Mars's geophysics and climatology, and provided many reference datasets on the red planet. By helping scientists understand the nature of water reservoir and Mars, and the ancient Mars's possibly "wet" environment, many of their findings are of interest to exobiology. Mars Global Surveyor experiments were as follows:

- The *Mars Orbiter Laser Altimeter* (MOLA), which created the most accurate global topographic map of any planet in the solar system, giving scientists elevation maps precise to within about 0.3 m in the vertical dimension with a global resolution of typically less than 2 km (Smith et al. 2001). The topography and geodesy data identified pathways for the flow of past water and the locations, sizes, and volumes of water flows and reservoirs like the polar caps. The Laser altimeter was also used to detect ► [CO₂ ice clouds](#) in the polar night and monitor the amount and distribution of condensed carbon dioxide. In June 2001, part of the laser reached the end of its life, but a sensor continued to detect changes in surface brightness in the near infrared part of the spectrum.
- The *Mars Orbiter Camera* (MOC) science investigation used three instruments: a narrow angle camera that obtained grayscale (black-and-white) high-resolution images (long strip 3 km wide with typically 1.5–12 m per pixel), a red-and-blue wide angle camera for context (240 m per pixel) and a daily global imager (7.5 km per pixel). MOC operated in Mars orbit between September 1997 and November 2006. It returned more than 240,000 images. The high-resolution images allowed numerous key discoveries on Mars geomorphology (Malin and Edgett 2001), including the presence of numerous layered deposits (Malin and Edgett 2000b) and even deltas, which appears to have been formed in liquid water environment (Malin and Edgett 2003); the presence of ► [gullies](#) probably created by flowing water in geologically recent times (e.g., a few millions years ago) (Malin and Edgett 2000a).
- The *Thermal Emission Spectrometer* (TES) monitored the Martian surface and atmosphere using thermal infrared spectroscopy (from 6 to 50 μm with either 5 or 10 cm^{-1} resolution) together with a bolometric visible-NIR (0.3–2.9 μm) measurement. TES systematically monitored the Martian climate (retrieval of the atmospheric temperatures, dust loading, clouds, ► [polar caps](#), water vapor) from the beginning of the mission until a failure on August 31, 2004. It provided reference climatology (Smith 2004) and an unprecedented understanding of Mars meteorology. Surface monitoring allowed the mapping of the ground albedo and thermal inertia, and the retrieval of the abundance of several minerals (Christensen et al. 2001a). In particular, in specific locations, TES detected some crystalline ► [hematite](#), an iron oxide, whose formation often requires the presence of liquid water (Christensen et al. 2001b). Hematite was detected in ancient sedimentary regions on Mars, such as Meridiani, south of Arabia Terra. Meridiani was later the chosen site for in situ exploration by the Mars Exploration Rover Opportunity, which discovered an interesting terrain in which liquid water is thought to have played a key role.
- The *Magnetometer* combined with an electron spectrometer (MAG/ER) was designed to study the magnetic properties of Mars surface and its ionosphere (Acuña et al. 2001). It discovered that while Mars had no global ► [magnetic field](#) generated in the planet's core, significant fields could be detected in small, particular areas of the ► [crust](#) in the most ancient terrains on the planet. These are the vestigial signal of an ancient and once powerful magnetic field, capable of magnetizing the surface. This ancient field may have protected the early atmosphere from gas escape induced

by the solar wind, and contributed to the ancient Mars habitability.

- The *Radio Science Investigations* (RSI) used measurements of the Doppler shift of radio signals sent back to the Earth to determine a model of the Mars gravity field. The analysis of the signal passing through the atmosphere allowed the monitoring of the density and temperature of the lower atmosphere and of the ionosphere properties.

Mars · NASA · Orbital measurements · Water

Definition

2001 Mars Odyssey, a name inspired by the works of the science fiction writer A.C. Clarke, is a ► [NASA](#) orbiter that was launched in 2001 to study the surface of ► [Mars](#) from orbit.

Overview

Mars Odyssey is still active and holds the record as the longest lived spacecraft in Martian exploration. Launched on 7 April 2001, the orbiter's instruments continue to contribute significantly to our understanding of Mars. The science objectives of the mission are wide ranging, but the theme “follow the water” is of particular importance. Other objectives include analysis of the surface elemental and mineralogical composition of the planet, indications of geological processes, such as volcanic activity, and measurement of the radiation environment in preparation for human exploration. These objectives were accomplished using the instruments THEMIS (The Thermal Emission Imaging System), the GRS (Gamma Ray Spectrometer-Neutron spectrometer), and MARIE (the Mars Radiation Environment Experiment). Mars Odyssey also serves as an important relay for the continuing ground-based rovers,

Spirit and Opportunity, the Mars Exploration Rovers (MERs).

The mission has been very successful. In particular subsurface water ice was detected in the form of elemental hydrogen in the near subsurface (below a few centimeters of dry sediments) in both hemispheres above about 60 latitude by the GRS instrument. Other areas of hydrogen concentration, for example, Arabia Terra, are most likely related to the presence of hydrated minerals or possibly to subsurface ice. Geomorphological evidence for the presence of water in the past (and possibly in more recent times) was revealed by the infrared camera THEMIS, which takes images during the day and at night, thus documenting subtle differences in the terrain that help distinguish features, such as channels features cut by water and melted snow, as well as sediments deposited by water. The detection of water ice is important for assessing water resources for future human exploration.

THEMIS has also mapped mineralogical variation in the surface composition of Mars and its results are pivotal to helping chose landing sites for the various Mars missions, Mars Exploration Rovers, Phoenix, Mars Science Laboratory in Gale Crater, Mars 2020 in Jezero Crater, as well as the European/Russian ExoMars 2022 mission that will land in Oxia Planum. Evidence for rocks with a felsic (i.e., rich in feldspath minerals) composition, as well as olivine-rich rocks, were detected, documenting the wide variety of rock types on the surface of the planet. The former represent evolved lavas and indicate a complex volcanic history for the planet. The latter, on the other hand, indicate little alteration of the original basalts during much of Mars' history. The THEMIS instrument was also designed to detect "hot spots" on Mars, which may correspond to local geothermal or hydrothermal activities. This research – of high interest with regard to the possibility of life in the near Martian subsurface – has been unsuccessful. Such spots may not exist or be very rare.

Measurement of galactic cosmic rays and solar energy particles by the instrument MARIE is important for determining the radiation environment to prepare human exploration.

Given its longevity, Mars Odyssey is turning its instruments on the moons of Mars, Phobos, and

Deimos, documenting changes in the physical properties of the Moons that will be useful for moon missions like the Japanese Martian Moons eXploration (MMX).

Finally, Mars Odyssey serves as an important relay center to transmit instructions to, and information from, vehicles on the surface of Mars.

MOM Mars Orbiter Mission

Definition

Mars Orbiter Mission (MOM) is India's first mission to Mars. It was approved for a total project cost of \$69 million in 2012 (actually \$74 million). It is, to date, the world's least-expensive Martian

mission. It was launched by a Polar Satellite Launch Vehicle (PSLV) on November 5, 2013, and inserted into Mars orbit on September 24, 2014 (Negi et al. 2020). The mission orbit is a wide ellipse (372 km x 70,000 km), inclined of 150° , with an orbital period of 65 h.

The small satellite, roughly a cube with of 1.50 m side, with a dry mass of 435 kg (Launch mass 1335 kg) has a power of 840 W provided by three solar panel energy generators (1.40×1.80 m).

It carries a science payload weighting 13.4 kg which includes five instruments (Kumar and Chauhan 2014).

- MCC: Mars Color Camera Mars Color Camera (MCC) operates in visible range from 0.4 to

$0.7 \mu\text{m}$ and uses a classical RGB Bayer pattern and has 16 modes of exposure to image the surface of Mars.

- TIS: Thermal Infrared Imaging Spectrometer. It can be operated day and night and it is mapping the mineralogy of the surface and monitor the concentration of CO_2 .
- MSM: Methane Sensor for Mars is a spectrometer analyzing the reflected sun light. After the orbit insertion, it appeared that because of a technical flaw the instrument is unable to measure methane concentration. It is now used to perform an albedo mapping.
- MENCA: Mars Exospheric Neutral Composition Analyzer: this quadrupole mass spectrometer is set to measure along the orbit, for four

Mars Orbiter Mission,

Fig. 1 Final integration of Mangalyaan on top of the fourth stage of PSLV25.

times an hour, the local neutral composition in a range from 1 amu to 300 amu.

- LAP: Lyman Alpha Photometer: this instrument is designed to determine the relative abundance of H and D in the upper atmosphere in order to evaluate the hydrogen and water escape in space.

The Mission is primarily a technological mission (Aruman and Satish 2015). Results include new data sets on exospheric composition, maps of the Phobos and Deimos moons, surface remote sensing, dust variability, and turbulence in the solar plasma.

Note that after approved registration the data from MOM are freely available for worldwide scientists at Indian Space Science Data Center.

Mars Pathfinder

Claude D’Uston

Géophysique Planétaire & Plasmas Spatiaux, Institut de Recherche Astrophysique et Planétologique, Toulouse, France

Definition

Mars Pathfinder was the second discovery class mission of NASA. It was sent to planet ► [Mars](#) in order to demonstrate the capacity to deliver safely and to operate remotely robotic equipment on the surface of Mars. Launched on December 4, 1996, it had successfully landed on July 4, 1997, in an ► [outflow channel](#) called Ares Vallis (19.30°N, 33.52°W) and worked until the end of September 1997. It consisted of a lander equipped with a panoramic camera and a meteorology package, plus a small rover called Sojourner that carried another camera and the alpha, proton, and x-ray spectrometer APX (Fig. 1).

The fully successful mission provided many images of the landing site, and information on the diurnal variations of the meteorological conditions and on the composition of soils and of a few rocks; these were basaltic rocks covered by wind-blown dust. It was a precursor for the subsequent ► [Mars Exploration Rovers](#) SPIRIT and OPPORTUNITY.

Synonyms

[MRO](#)

Definition

Mars Reconnaissance Orbiter (MRO) is a ► [NASA](#) mission exploring ► [Mars](#) from a quasi-circular polar orbit, about 300 km in altitude. Launched on August 12, 2005, it arrived on March 10, 2006, and is still operating, at least till the mid-2020s, much beyond its designed duration of two terrestrial years. Its prime goals are to perform high-resolution observations of the surface, the atmosphere, and the subsurface, as well as to characterize landing sites of in situ missions.

Overview

Mars Reconnaissance Orbiter (MRO) embarks six instruments and is capable to transmit to Earth ten times more data than previous missions. In particular, it enables to image the surface with unprecedented resolution (Fig. 1), both in the visible (20 cm footprint) and in the near infrared (20 m). It plays a unique role in deciphering the evolution of Mars, at all timescales.

MRO has been given the five following science objectives:

1. Characterize the present climate of Mars and its physical mechanisms of seasonal and interannual climate change.
2. Determine the nature of complex layered terrain on Mars and identify water-related landforms.
3. Search for sites showing evidence of aqueous and/or hydrothermal activity.
4. Identify and characterize sites with the highest potential for landed science and sample return by future Mars missions.
5. Return scientific data from Mars landed craft during a relay phase.

Six instruments were selected to achieve its goals and objectives:

- HIRISE (High-Resolution Imaging Science Experiment), a camera with unprecedented resolving capability: the pixel size can be as low as 20 cm, some six times better than the MOC camera on the NASA/MGS mission. When the mission will end, several percents of Mars surface will be covered.
- CTX (Context Camera), a wide-angle camera providing the optical context of the other instruments, in images 40 km in size, with a footprint of 8 m/pixel.
- MARCI (Mars Color Imager) produces each day a global image of Mars in five colors, to track changes in Martian weather (► [clouds](#) and atmospheric constituents). It monitors Mars atmosphere on diurnal, seasonal, and annual timescales.
- CRISM (Compact Reconnaissance Imaging Spectrometer for Mars) is an hyperspectral imager: in each pixel, some 20 m in size, CRISM acquires the entire spectrum, in hundreds of contiguous spectral channels covering the visible and near-infrared range (from 0.4 to 4 μm). This enables to identify both surface (ices and frosts, as well as minerals) and atmospheric (gas, clouds, and aerosols) constituents. Its spatial resolution is one order of magnitude better than that of the OMEGA

Mars Reconnaissance Orbiter, Fig. 1 Jezero Crater, the Perseverance Landing site, in an image overprinting the findings of different MRO instruments. (Image Credit: NASA/JPL-Caltech/MSSS/JHU-APL)

M

instrument on the ESA/► [Mars Express](#) mission. The counterpart is that each image is less than 10 km large: a few percents of the global Mars surface should be mapped by CRISM in this high-resolution mode.

- SHARAD (Shallow Subsurface Radar) is designed to search for potential water (liquid or ice) down some hundreds of meters below the surface, using electromagnetic waves at ~ 20 MHz. Coupled to potential discoveries made by the MARSIS instrument on ESA/► [Mars Express](#), capable of penetrating some kilometers with a reduced vertical resolution, SHARAD would finely characterize shallower aqueous layers with a tenfold better accuracy, of ~ 10 – 20 m.
- MCS (Mars Climate Sounder) is a ► [spectrometer](#), primarily operating in the thermal infrared (12 – 50 μm), designed to quantify the global water vapor and dust content of the atmosphere, as well as its temperature. When pointing at the limb, its vertical resolution is ~ 5 km. Its diurnal maps enable a global monitoring of Mars atmospheric evolution.
- Finally, the fine monitoring of the spacecraft orbit provides an investigation of Mars' gravity, as a means to sound local variations of, for example, crustal or polar cap thickness.

Together with Mars Express, MRO is building one of the most impressive Mars dataset ever acquired, enabling a profound revisiting of Mars History at all timescales, from its ancient times to its recent evolution. Noticeably, it has played an essential role in the high-resolution characterization of the surface composition, with an emphasis on the compounds possibly recording astrobiologically related processes. As such, it contributed as the prime source of evidences to the selection of the recent NASA roving mission, Curiosity at Gale Crater and Perseverance at Jezero crater.

In addition to performing essential remote observations of Mars, MRO is one of the relay assets of in situ missions, necessary for transferring data from and toward Earth.

MSR

Definition

The Mars Sample Return (MSR) mission aims to retrieve soil, rock, and atmospheric samples from Mars to bring them to Earth to study them thoroughly in Earthian laboratories. MSR will be a key milestone in the exploration of ► [Mars](#) and the resolution of key questions in astrobiology and planetology.

The ambitious scientific objectives, the ► [planetary protection](#) issues, and the overall technical complexity of the program put a huge challenge on the design, development, and operations of this project which requires several successive space missions and significant ground infrastructures.

After several years of cooperation on the definition of a reference architecture proposed by an international working group, a joint letter of intent was signed in 2018 between NASA and ESA to set up a suite of missions to deliver Martian samples on Earth by the 30s.

History

Retrieving sample from Mars is a long-lasting dream of planetologists and astrobiologists. NASA organized workshops as early than 1973, before the landing of the Viking spacecrafts. In the United States the National Research Council issued several reports on the handling of the samples as they arrive on Earth (National Research Council [1997](#), [2002](#)). At the end of the years 1990, NASA and CNES began preliminary discussions to develop a cooperative project named “MARS PREMIER” in France. After several joint preliminary studies, the project was considered as too difficult, risky, and expensive, and therefore it was abandoned in the early years 2000. But the conceptual development of the handling of the Martian samples led to the development of what is known as the “Draft Test Protocol” ([2002](#)). In the same time frame, several space agencies, gathered in the International Mars Exploration Working Group (IMEWG), agreed to set up a dedicated working group to study an International Mars Architecture for the Return of Samples (known as iMARS). A first report was issued in July 2008 (iMARS [2008](#)). Later it serves as a base of a second working group (iMARS2) which was chartered in 2014 with two panels devoted, respectively, to engineering on the one hand and science and earth operations on the other hand. The group issued a detailed report in 2018 (Haltigin et al. [2018](#)).

At the same time, several groups issued recommendations about the science objectives (Mars Science Planning Group- Beaty et al. [2019](#)) the handling of extraterrestrial samples (Eurocares) (Smith et al. [2021](#)), and the safety measures to take in order to comply with the planetary protection recommendations through the COSPAR planetary protection panel. All this work led to the agreement between NASA and ESA to plan

and organize a joint Mars sample mission beginning as early as 2020 with the launch of Mars 2020 and its rover named Perseverance.

Overview

Based on the former studies the mission is rather complex and challenging with a lot of interfaces between instruments and hardware developed in different countries and operations split also between various centers either in the United States and Europe.

Scientific Objectives

The more Mars is known, the more the planet is attracting planetologists and astrobiologists. The physical and geological properties of the planet are now quite well documented; thanks to several successful space missions. The former discoveries lead to questions that have to be answered by the exploration of selected Martian sites and the in-depth study of the geological record to answer the following main items:

- Has life ever arose on Mars?
- What are the processes and history of climate on Mars?
- How to determine the evolution of the surface and the interior of Mars?
- How to prepare for the future Human exploration of Mars?

To collect relevant information on these issues, a Mars Sample Return (MSR) program will offer the opportunity to answer to these items. Indeed, returning carefully selected and documented samples, for analysis in terrestrial laboratories, provides three fundamental advantages:

- Complex preparation of the samples for these analyses is feasible.
- A wide variety of instruments can be used including very large and powerful facilities.
- Adaptation of the studies to the discoveries

The selection of the returned samples is fundamental for the value of the returned samples.

These requirements impact severely the selection of the landing site, the sampling itself, the sample, and the sample preservation.

Program Layout

Based on the report of the working groups mentioned earlier and the joint work of the agency centers, a reference design was selected (Fig. 1).

The program includes at least three launches from the Earth and one launch from the surface of Mars.

The first launch occurred on July 28, 2020, with the launch of Mars 2020 which led to the successful landing of the rover Perseverance at the surface of Mars (February 18, 2021) in the Jezero Crater.

The rover built by the JPL explores an ancient delta and have begun to collect samples (Fig. 2) encased in the RSTA. In the current version of the program, these RSTA will be dropped in different places to be collected further.

Later, a US rocket will launch the SRL with a MAV and the European SFR.

The SFR will collect the RSTA to bring them to the SRL. They will be placed in the OS which will be safely closed when the task will be completed. Note that Perseverance can collect 41 samples but that in the present configuration the OS can retrieve only 33 RSTA. The OS will be placed on top of the MAV. The MAV will be launched to put the OS (roughly the size of a basketball ball) on an appropriate Martian Orbit.

About the same time of the launch of the SRL, Europe will launch ERO to Mars to be placed in orbit. ERO will be tasked after the launch of the MAV to optically identify the OS, and to set up a rendezvous. A US built system will then capture the OS. Then this system will do operations necessary to condition this container, to place it in the EEV and to certify that it is finally tightly sealed in the EEV. At the appropriate orbital window, ERO will fire its engine to come back toward the Earth. In the vicinity of the planet, the tightness of the conditioned OS will be finally checked. The EEV will be released from ERO for a direct Earth atmospheric entry and a hard landing (planned in the Utah Test and Training Range). ERO will be
